Education and the Nation.

On Sunday, November 27, Mr. Fisher, President of the Board of Education, speaking in Whitefield's Mission, London, on "Our Schools," said:

"Education is a great unifying influence, not only between classes, but also between nations. The estranging influences between man and man are not rooted in the externals of situation or wealth, but are founded in differences of intellectual acquisition and of intellectual and moral outlook. There still persists the delusion that the education of the poor must be different, not only in amount, but also in quality, from the education which is at the service of the more affluent members of the nation. But the poor, even more than the rich, stand in need of the best possible education, since they lack the home advantages of the wealthy. Indeed, in the crowded areas of the cities the school plays an even greater part than the home in the formation of the national mind. The elementary school may not give all the results we are entitled to expect, though there has been great progress made in the last generation through the development of a spirit of humanism in the schools. It will not become fruitful in result until something is done to provide education for the vital period of adolescence."

This was the spirit that animated Mr. Fisher in the drafting of the measure which culminated in the Education Act of 1918, and served to mark the public appreciation of the benefits of education and the great progress made since the Education Act of 1902. Mr. Fisher stated that day continuation schools were provided for in the Education Act of 1918, but, owing to financial circumstances, at the present time they could not develop the system adequately. He added that the children of the nation needed more schools, more books, and better teachers, and if the nation was in earnest they would assuredly get them in time. Yet the Board of Education has continually thwarted the progressive efforts of the more enterprising local authorities in the provision of new schools; it hampers the provision of Central Schools in London even where such provision can be made by the reorganisation of existing elementary schools, and it checks the development of schools where physically defective children can receive remedial treatment.

There has arisen—and it is an extremely hopeful sign of the public interest in the value of education—a strong demand for the advantages of higher education, and thousands of children in all parts of the country are eager for admission to secondary schools; but the Board offers no encouragement to that end; in fact, it has sanctioned the raising of the fees in such schools, thereby preventing the poorer children from taking advantage of them, and

the same policy is being pursued with respect to the much-needed nursery schools for children under five. Day continuation classes during two years, as provided for by the Act, for young people who have left the elementary school at fourteen in order to enter into employment, are, except in the London area, practically a dead letter, the Board refusing its sanction to the fixing of the appointed day.

The Committee of business men appointed by the Chancellor of the Exchequer, with Sir Eric Geddes as chairman, to consider the national expenditure with a view to drastic economies in the various spending departments has presented its Report to the Cabinet, but its full details have not been made public. It is rumoured that there is a proposed reduction in the total estimates for the year 1922–23 of 195,000,000*l.*, of which the education estimates are responsible for 16,000,000*l.* As showing the spirit in which this question has been approached, Lord Inchcape, one of the influential members of this Committee, and the chairman of the P. and O., said, at a recent meeting of the shareholders of his company, that "education is an excellent thing in its way, but there are limitations to its economic usefulness." Lord Haldane, at a meeting held at London University on December 17, arranged by the London Head Teachers' Association, dealt effectively with Lord Inchcape's observations, and showed how much the progress of the nation in every department of industrial life and even in his own particular business of shipping has been due to education. He said:

"Lord Inchcape could not sail a single steamer but for the education of the great inventors and men of science which made it possible, nor would his staff know how to handle the instruments but for the training they have received from their teachers. Modern business cannot stand still, neither can education. Other nations realise the value of education, and will get ahead of us if we do not; if we neglect it, hard times will come, when we shall be driven belatedly to reverse the policy threatened to-day in order to recover our resources and progress, which will have failed us through our misunderstanding of the true meaning of economy."

In this respect the decision of the Treasury to reduce the grant to the universities from 1,500,000*l.* to 1,200,000*l.* will seriously hamper these institutions in their endeavour to get and to retain competent teachers, and will impede scientific research on which a further advance in knowledge and especially industry, alike in the spheres of manufactures and of agriculture, so largely depends. The joint meeting of the general council of the Trade Union Congress and the Labour Party Executive, held in London on December 14, views this policy with profound disapproval, which can do virtually nothing, it says, "to relieve the national finances, but which will be a serious blow to higher education."

An important manifesto has recently been issued by the Teachers' Registration Council, entitled "Education and National Life," for presentation to his Majesty's Ministers and in the expectation that it will be signed by many eminent men and women. It refers to the national danger which attends any attempt to reduce expenditure on education, and urges that the recent extension of the franchise has made it the more necessary to open all possible avenues of knowledge and enlightenment as preventives of error and half-truths in politics, economics, and social relationships. A complete and generous system of education will fortify the State against civil unrest and strife, while serving to widen the vision and enrich the lives of individuals. We were led in the tragic ordeal of the war to perceive the faults of our previous educational system and to frame the new proposals embodied in the Education Act of 1918. But that measure is not really in operation, and the newly awakened desire of working people for further knowledge is left unsatisfied. The signatories recognise the need for a careful survey of our national resources and for thrift in all public and private expenditure, but hold that thrift should be exercised with discrimination and not so as to curtail educational opportunity. They conclude with the desire to see our country take its place in the van of civilised and enlightened communities and regard public expenditure on education as a wise investment which will bring to this and succeeding generations the rich rewards of civic greatness and private contentment.

It is to be hoped that this weighty manifesto from an influential body of well-wishers to education may receive speedy and favourable consideration at the hands of the Government, in order that the provisions of the Education Act of 1918 may be put into practical operation without further delay, and also that the full grant of 1,500,000*l.* be restored to the universities so as to encourage research in all departments of knowledge and give them the opportunity of fully developing their resources in the vital and permanent best interests of the nation.

Fifty Years of Electrical Science.

Fifty Years of Electricity: The Memories of an Electrical Engineer. By Prof. J. A. Fleming. Pp. xi + 371. (London: The Wireless Press, Ltd., n.d.) 30*s*. net.

IN giving us his memories of the past fifty years, Prof. Fleming has compiled a noteworthy work. "The book makes no claim," he writes, "to be a systematic treatise on electricity or electrical engineering, but is simply intended as an attempt to place before the intelligent general reader a fairly comprehensive view of the chief triumphs of applied electricity during the last half-century." The intention is carried out with the clearness of style and the lucidity of expression we have long learned to expect from the author. He may be assured that, as he hopes, it will "assist junior engineering students in obtaining a preliminary acquaintance with the outlines of a subject they will study in greater detail in other books," while to those who are not going to be professional physicists or engineers it will give a far more useful appreciation of what electricity is and what it has done than they gain from their attempts to verify Ohm's law or measure the magnetic moment of a piece of magnetised steel. Electrical progress lends itself in a very special way to treatment of this kind, but if it were possible to do for other branches of science what Fleming has achieved for his the gain would be very great.

From Sturgeon, who in 1825 constructed the first electro-magnet, to Einstein, whose work is referred to in one of the later chapters of the book, is nearly twice fifty years, but the work of the first half of the period, though fundamental, is passed over briefly in an introductory chapter. We are reminded of the importance of Sturgeon's discovery, of its extension by Joule and Faraday and Henry, and its almost immediate application to the electric telegraph by Cooke, Wheatstone, and Morse, culminating in the Hughes printing telegraph, for which the first U.S. patent was secured in 1855; the laying of the first Atlantic cable, 1857–58, which survived for only two months; the work of William Thomson, Lord Kelvin, based on his Royal Society paper of 1855 on "The Theory of the Electric Telegraph," leading to the mirror galvanometer (1858) and the siphon recorder (1867) after the successful laying of the 1866 cable.

Electrical telegraphy in England was at first developed entirely by private enterprise, and in 1870, when the business was taken over by the State, the various companies owned altogether some 16,000 miles of lines. Up to this time, the date at which Prof. Fleming's memories start and his detailed history begins, electrical engineering had been almost entirely concerned with telegraph work. The Society of Telegraph Engineers and Electricians—afterwards to become the Institution of Electrical Engineers—was in 1870 the only electro-technical society in England.

But the seeds of a greater development had been planted. Electro-magnetic induction was discovered by Faraday in 1831. From that followed the early magneto machines of Saxton (1833) and Clarke (1835); the Siemens armature was devised in 1856, the Gramme ring by Pacinotti in 1860. Wilde, in 1850, had used electromagnets instead of permanent magnets for the field-coils of a machine, and this was followed, in 1867, by the invention of the dynamo; the machine became self-exciting.

The account of these fifty years occupies some fifty pages of Prof. Fleming's book; for the next fifty the remaining 300 pages barely suffice. In six chapters details are given of the advance in all directions. Telegraphs and telephones, from Hughes's first printing instrument and Graham Bell's early telephone to the modern multiplex type machines and the automatic telephone exchange, are all described. Then we have dynamos, alternators, transformers, and motors, from 1870 to 1920, from the first Gramme and Siemens machines of some few kilowatts to the giants of the present day. Another chapter treats of electric lamps and lighting; yet another of supply stations, storage batteries, and railways; while fifty pages are devoted to electric theory and measurements, from Kelvin and the work of the first British Association Committee on Electrical Units in 1861–62 to Maxwell and theories of the ether, the discoveries of J. J. Thomson and Rutherford, and the influence of Einstein on modern physics. The final chapter deals with wireless telegraphy. Commencing with the theoretical work of Maxwell and Hertz, it passes in review the experiments of Hertz, Lodge, and Admiral Jackson, concluding with those of Marconi and his associates. An account is given of the valve detector devised by the author in 1904, and of the improvement due to Dr. Lee de Forest, by which it became the triode valve and amplifier for wireless waves.

This very brief *résumé* will indicate the scope and extent of the work. The limitations of space prevent any detailed account, and indeed no such account is necessary beyond the statement that all important developments in electrotechnics of the last fifty years are described with the well-

known skill of the author, who has added to our libraries a most useful and interesting work. Both he and the Wireless Press, which has produced the book, may be cordially congratulated on the result of their labours.

Fermat's Last Theorem.

Three Lectures on Fermat's Last Theorem. By L. J. Mordell. Pp. vii + 31. (Cambridge: At the University Press, 1921.) 4*s.* net.

THE "last theorem of Fermat" states that if x, y, z, p denote positive integers, the equation $x^p + y^p = z^p$ is impossible if p exceeds 2: thus no cube can be the sum of two cubes, and so on. If the theorem is true when p is 4, or an odd prime, it is true for all other integral values of p. For three centuries this theorem has baffled the efforts of all who have attacked it, although it has attracted the attention of all first-rate arithmeticians, and a great number of amateurs. For $p = 3, 4, 5, 7$ comparatively simple proofs have been discovered; but so far none of these has led to a complete generalisation.

The first great advance in the theory was made by Kummer, in connection with his researches on cyclotomic integers. He showed that if the theorem is false for any particular odd prime p, then p must not be a factor of the numerator of any one of the first $\frac{1}{2}(p-3)$ numbers of Bernoulli. This very recondite test rules out all values of p below 100 except 37, 59, 67. By additional criteria Kummer was able to prove the theorem for these exceptional primes, and hence for all values of p from 3 to 100 inclusive.

Not many years ago (1907) a prize of 100,000 marks was set aside for the first who succeeded in giving a complete proof or disproof of the theorem. Quite recently, new criteria, independent of Kummer's, have been discovered, which have to be satisfied by odd primes p for which the theorem is false, and the simplest of these is the condition $2^{p-1} \equiv 1 \pmod{p^2}$, discovered by Wilferich in 1909. Other tests of a more or less similar kind have been accumulated, and the net result is that any value of p for which the theorem is false must exceed 7000. Gauss's tables of quadratic forms warn us not to draw any conclusions from this result; in fact if N is any *assigned* integer, however large, a proof that the theorem is true unless $p > N$ gives us no information about the truth or falsity of the theorem in general.

Mr. Mordell's lectures give a clear and interesting account of the history and present state of this subject. Lecture I. gives a statement of the theorem, and a summary of the work done by Kummer's predecessors; Lecture II. is on Kummer's researches, and more recent investigations of similar type; and Lecture III. gives an account of various results obtained by Libri, Sophie Germain, and others. Full references are given to the original papers, so that a reader within reach of a good reference library can make himself acquainted with details of all that has been done hitherto.

A perplexing circumstance, often alluded to, is the fact that, in a private note, Fermat distinctly asserted that he had proved the theorem. Now Fermat was never convicted of a false assertion, and only once of a wrong conjecture; on the other hand it is extremely improbable that Fermat's proof, if he had one, was in any way analogous to the work of Kummer and his successors. It is not, perhaps, unreasonable to hope that a proof may be found, some day, derived from Diophantine analysis proper, combined with a process of induction, and possibly with some application of analytical geometry, or theory of equations, or both. A really gifted youth, approaching the problem without knowledge of modern analysis, might throw a quite new and unexpected light upon it.

Mr. Mordell's pamphlet ought to do much to stimulate our rising mathematicians, and we hope that it will have a large circulation.

G. B. M.

Chemistry of Coke-oven and By-product Works.

Coke-oven and By-product Works Chemistry. By T. Biddulph-Smith. Pp. x + 180 + 7 plates. (London: Charles Griffin and Co., Ltd., 1921.) 21*s.*

THE author states in the preface that his object in compiling this book is to furnish a concise manual covering, so far as space will allow, the general work required for the chemical control of coke-oven and by-product works. As regards the variety of subjects treated, he has doubtless achieved his object, but it is to be regretted that the apparent exigencies of space have caused the manual to become so concise in certain sections as to detract appreciably from the value of the work as a whole.

The most valuable section of the manual is that relating to the coal-tar naphthas. There is no doubt that the author has taken considerable pains to collect together the work of some of our best analytical chemists on methods of evaluating the constituents of coal-tar naphthas—work which

was carried out during the war period when the adequate examination of these products was a matter of such great importance. Although most of the methods dealt with have already been described either in technical journals or in the proceedings of technical societies, chemists will welcome the accumulation of this information within the covers of one volume. Moreover, the admirable summary of "The Constituents of Coal-tar and their Properties," compiled by Dr. Spielman, appears in a revised form as an appendix, and the inclusion of this information may prove useful to the coke-oven chemist by saving reference work.

The rest of the book is disappointing. In describing analytical methods the author has obviously attempted to do more than supply indications of the method recommended by him, but has failed to furnish sufficient detailed information to be of real service to the works chemist.

The chapter dealing with the fractions of coal-tar other than the naphtha fraction is meagre, and the weakness of this section accentuates the fact that chemists have not yet given adequate study to the analytical methods required in the examination of the heavier fractions of coal-tar, which are no less important than the naphtha distillate. It is in this section of the book that a recommendation appears which would have shocked those older and well-established chemists who attempted to teach us our subject, and who, not living in these times of efficiency systems and labour-saving devices, paid due reverence to instruments by which accurate measurements might be made. The recommendation refers to the crystallisation of crude tar acids, the instructions being to cool the liquid, "stirring continually with a Fahrenheit thermometer graduated in tenths of a degree."

The treatment accorded in other sections of the book to the analysis of gases, calorimetry, and the examination of chemical products made and required in the recovery works is all too brief. The analysis of coal-gas, which is acknowledged to be so intricate as to require considerable experience before trustworthy results can be expected, is dealt with in a few pages, whilst the method of procedure recommended is archaic. The estimation of naphthalene is carried out by a method which would be quite unpractical if small quantities of ammonia were present in the gas, though no mention is made of this fact.

Finally, the manual contains the usual collection of tables and conversion factors in the second appendix—so useful to reader, author, and publisher.

E. V. EVANS.

Lichens.

(1) *Lichens.* By A. L. Smith. (Cambridge Botanical Handbooks.) Pp. xxviii + 464. (Cambridge: At the University Press, 1921.) 55s. net.

(2) *A Handbook of the British Lichens.* By Annie Lorrain Smith. Pp. vii + 158. (London: The British Museum (Natural History), 1921.) 6s. 6d.

(1) FOR many years botanists have been without a guide to the large mass of facts that have been added year by year to our knowledge of lichens. Miss A. Lorrain Smith has therefore done a good work in compiling a very comprehensive handbook on this group of plants. The growth of our manufacturing and even our garden cities proves fatal to all except a few insignificant lichens. They are driven away to those far-off parts of the country where the air is still fresh and pure. This circumstance very possibly, but the absence of any comprehensive handbook on, and guide to, the lichens certainly, is a reason why so little interest is taken in this group. Yet, ecologically, it is one of the most interesting groups. Lichens grow on the outskirts of vegetation, as pioneers of the plant world, preparing the way for moss, fern and flowering plant. They are most intimately in touch with the substratum in its virgin condition. Few ecologists, however, properly consider lichens. Anatomically, the lichen thallus very directly reflects the nature of the substratum. A great deal, however, still remains to be done in this direction. The elaborate and careful work of the late Abbé Hue has, unfortunately, not brought much morphological order into our knowledge of lichen structure.

The whole question of the dependence of one organism, whether animal or plant, on another, or even others, again whether animal or plant, is every day becoming of greater interest. The views of various lichenologists on this matter are placed before us by Miss Lorrain Smith, but the simple word symbiosis is the term most favoured. It does not define the relationship between alga and fungus in too great a detail. Terms like helotism (due, by the way, to Warming and not to Nienburg), parasitism, consortium, endosaprophytism, and others, may cover certain individual cases, but the relationship of alga to fungus certainly varies in different species, or possibly even in different individuals of one species growing under different conditions. There is no doubt that on the whole the lichen-fungus fully controls growth and reproduction of the gonidial algæ,

though within certain limits both take place freely. Lindau, however, has described how in certain hypophlœodic lichens the alga actually forges ahead of the fungus.

The various branches of the subject have been very fully dealt with by Miss Lorrain Smith, but we think that not sufficient reference has been made to Exsiccata, which have played such an important part in lichenological nomenclature. We also consider that the book as a whole is not well illustrated. Many of the line drawings are quite inadequate as illustrations in a handbook of this standard. The half-tone figure on p. 117 appears to us to be *Cladonia uncialis* rather than *Cladonia furcata,* whilst Fig. 135 on p. 416 does not recall to us *Parmelia omphalodes,* which it purports to represent. Apart from these blemishes, which we consider rather serious, the handbook is a storehouse of valuable information, and Miss Lorrain Smith deserves the thanks of all lichenologists and botanists for the care and thoroughness with which she has completed her task. Some readers might possibly object that they are left too much to draw general conclusions for themselves.

The price of the book, unfortunately, is prohibitive except for public and college libraries.

(2) We are sure that Miss Lorrain Smith's "Handbook of the British Lichens" will answer its purpose very well and help both botanist and collector to name their specimens, instead of being compelled to depend for this on foreign books. The book, however, is only a key to the "Monograph of the British Lichens," by Miss Lorrain Smith, the price of which, again, is well-nigh prohibitive. We may express the hope that this little book will help to create renewed interest in a group of plants the study of which was at one time keenly followed in this country.

O. V. D.

British Mineral Resources.

Memoirs of the Geological Survey. Special Reports on the Mineral Resources of Great Britain. Vol. 19, *Lead and Zinc Ores in the Carboniferous Rocks of North Wales.* By Bernard Smith. Pp. iv+162+3 plates. 1921. 5*s.* 6*d.* net. Vol. 21, *Lead, Silver-lead, and Zinc Ores of Cornwall, Devon, and Somerset.* By Henry Dewey. Pp. iv+72. 1921. 2*s.* 6*d.* net. (Southampton: Ordnance Survey Office; London: E. Stanford, Ltd.)

THE two volumes under notice form an important contribution to our knowledge of British mineral deposits, and afford satisfactory evidence that Dr. Flett is continuing energetically the valuable series of reports inaugurated by his predecessor at the Geological Survey. The scheme of both volumes is identical and is upon the lines with which previous reports had already familiarised us, but the economic importance of the deposits discussed therein differs very widely. The lead and zinc veins of North Wales have not only been highly productive in the past, but also may well take rank in the future among the leading British lead-producing mines, whilst those of the south-west of England present little more than academic interest. Needless to say, none of the mines discussed in either volume is at work just now; in fact, in the whole of Great Britain there is not a single lead or zinc mine capable of working save at a loss at the present time, probably a result of Government interference in the control of industries.

In North Wales such well-known mines as the Halkyn mines and others in the Holywell-Halkyn area, the Minera mines and other adjoining mines in Denbighshire are fully described, together with numerous less important mining properties. It is abundantly clear that in all these cases the great difficulty to be overcome is the enormous influx of water, which has rendered the economic working of these mines practically impossible. An interesting account is given of the various deep adit drainage schemes by which it is proposed to unwater some of the more important mining areas down to a considerably greater depth than has hitherto been reached. Although he does not specifically say so, it would appear that Mr. Bernard Smith entertains no doubt of the ore holding down to the greatest depth that would thus be rendered available. Incidentally he shows that the 35,000*l.* which the Government advanced for unwatering the Halkyn area have been wasted and have never yielded any return whatever. It can only be hoped that some satisfactory scheme for unwatering this area may be devised and carried into execution, though it is difficult to see how this can be done until British lead-mining reaches a sounder economic position than that with which it is faced to-day.

As regards the lead mines in Cornwall, Devon, and the Mendip Hills, it can only be said that there is practically no likelihood at all of any serious revival of the lead-mining industry in these parts, and it is fortunate that the task of collecting information as to the past history of these mines has been undertaken before it is too late. Mr. Dewey has done a useful piece of work in carefully compiling an account of these mines, which will be especially interesting to the student of mineral deposition.

H. LOUIS.

Our Bookshelf.

Guide Pratique de Sylviculture. Par Dr. F. Fankhauser. Troisième édition française par M. Petitmermet. Pp. 348. (Lausanne, Genève, et Paris: Payot et Cie, 1921.)

DR. FANKHAUSER'S elementary text-book on forestry is used in Switzerland for the instruction of agricultural students and working foresters; that it has great merits is evidenced by its appearance in five German and three French editions. The work is remarkable for its clear style, excellent illustrations, and admirable choice of subject-matter. The introduction, concerned with the utility of forests, explains their importance in creating industries, in regulating water supply, in preventing erosion of the soil, etc., in a country like Switzerland, where there is so much of what the author calls "absolute forest soil," or land that cannot be put under any other form of cultivation. The forests of Switzerland cover, in fact, 2,300,000 acres, about 23 per cent. of the total area of the country, and are credited with a production of about 42 cubic feet of timber per acre annually.

The first part of the book—forest botany—after some elementary notes on morphology and physiology, deals separately with each forest tree, giving its botanical characters, distribution, reproduction, growth, sylvicultural features, enemies, diseases, wood, and other products. Only one foreign conifer is included, *Pinus strobus*, and it is evident that exotic trees, like Douglas fir, Sitka spruce, and Japanese larch, so much favoured in England for planting at present, are not valued in Switzerland as yet. The next part of the book, concerned with the art of sylviculture, is an excellent summary of the different kinds of forests and how they are created, maintained, and cared for. Much attention is paid to practical subjects, like choice, collection, testing, and sowing of seeds of forest trees, nursery treatment, artificial plantations, natural regeneration, and thinnings.

Other chapters deal with utilisation, a subject which includes felling and transport of timber, and the properties and uses of wood, and with the protection of forests from wind, frost, fire, drought, insects, fungi etc. The conclusion of the work is devoted to the simple engineering and building problems that are handled daily by foresters in Switzerland.

The Principles of Immunology. By Prof. H. T. Karsner and Dr. E. E. Ecker. Pp. xvii + 309 + 2 plates. (London: J. B. Lippincott Company, 1921.) 21*s.* net.

THE researches of Pasteur on immunisation against fowl cholera, swine erysipelas, anthrax, and rabies, and the discovery by Behring and Kitasato of the antitoxic properties of the blood serum, constituted the beginnings of the science of immunology, which since 1890 has grown to incredible dimensions and in every direction has insinuated itself into the domains of practical diagnosis and therapeutics. It is no longer within the capacity of one or even two individuals to deal authoritatively with the subject, although this was attempted, and with a fair measure of success, a year or two ago by such a master as Jules Bordet. Naturally many text-books exist on immunity, and the present work of Karsner and Ecker must be ranked as one of the more successful among these. The authors have handled a goodly part of the periodical literature, and have applied to their reading and study a critical acumen which is conspicuous by its absence in most books of this class. Their knowledge is of a most modern kind, and they have thrown over allegiance to the Ehrlich "side chain" hypothesis which dominated immunology for so many years. Naturally in a work of its size Karsner and Ecker's book is highly condensed, and is, in fact, restricted to fundamental principles. They state that it is primarily designed for medical students and busy practitioners. As a text-book for students working for the higher examinations it can be cordially recommended, and it may possibly be read with profit by the more intellectual types of practitioners who have previously prepared themselves for the intricacies of the subject by the perusal of some more elementary work on the subject.

We notice a number of misprints, especially in the names of several of the authorities cited, and it may be said that some of the few illustrations are crude. Otherwise it may be recommended as an accurate guide to those who wish to study the subject with profit in the periodical literature of the day.

W. B.

When Buffalo Ran. By G. B. Grinnell. Pp. 114 + 8 plates. (New Haven: Yale University Press; London: Humphrey Milford, Oxford University Press, 1920.) 10*s.* 6*d.* net.

THE supposed autobiography of a Red Indian boy of some seventy years ago, when the veteran author was himself a small boy. The tribe is not mentioned, doubtless with intention; but Mr. Grinnell probably had in his mind the Cheyenne, which he knows so well. Anyhow, the book is not for ethnologists, but for boys, and the one on whom we have tried it pronounces it "topping." Written in the simplest English, without affectation, the story brings out all the noblest features of the tribal life that has passed away. There is abundance of sympathy, but no sentimentality.

High Tension Switchgear. By H. E. Poole. (Pitman's Technical Primers.) Pp. ix + 118. (London: Sir Isaac Pitman and Sons, Ltd., 1921.) 2*s.* 6*d.* net.

IN this brief introduction to a large subject, the author contents himself with a summary of the principal features of present practice in the design of oil-break switches for the voltages in common use in this country. A few notes on isolating links, surge arresters, high-tension fuses, and testing pressures have also been inserted.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Atmospheric Refraction.

THE correspondence on terrestrial refraction from Mr. Mallock and Dr. de Graaff Hunter in NATURE of June 9, p. 456, and August 11, p. 745, raises a paradox which I think must have puzzled many readers of NATURE besides myself. Mr. Mallock is, of course, quite correct in stating that the diminution of density of the air observable under ordinary conditions is practically linear for moderate increases of height above the earth's surface, and that, consequently, the refractive index of the air may for moderate increases of altitude be taken as diminishing linearly at such a rate that it would reach vacuum value at the height H of the homogeneous atmosphere. Dr. Hunter is equally correct in pointing out that Mr. Mallock's reasoning, based on the above-mentioned observational fact, leads to a value of k, the coefficient of terrestrial refraction, which is almost exactly twice as great as that found by observation under ordinary conditions. Dr. Hunter does not, however, point out what I think is the real fallacy in Mr. Mallock's argument.

The difficulty is not to be got over by any consideration of temperature-gradient in the air, although it is well known that variations in the temperature-gradient constitute the chief cause of variations in terrestrial refraction. The only way in which temperature-gradient could affect Mr. Mallock's result would be by its requiring a change in the value (4·32 sea-miles) which he adopts for the height H of the homogeneous atmosphere. Whether we calculate H for air at a uniform temperature, as is usually done, or on the assumption of a diminution of temperature with increase of height at the rate ordinarily observable (say 1° C. for each 200 metres), we obtain a value of H which is nearly the same as that used by Mr. Mallock in his argument.

May I suggest that the solution of the riddle is to be found in Mr. Mallock's supposition of a "*plane vertical* wave-surface starting from P," whereas the rays of light from a terrestrial point must give rise to an approximately *spherical* wave-surface? In the diagram (Fig. 1), which represents a vertical section through the homogeneous atmosphere with the curvature of the earth neglected for simplicity, a plane wave-surface HPO would change its position to BAC in the time t, where HB and OC are proportional to the velocities of light at H and O. But in that time rays from a point P would reach points D and E, such that $PD-PA=\frac{1}{2}(PB-PA)$ and $PA-PE=\frac{1}{2}(PA-PC)$, because the average velocity along PD would be the mean of the velocities at P and H, and, similarly, the average velocity along PC would be the mean of the velocities at P and O. It is easy to see that this gives a radius of refractional curvature exactly twice as great as that found by Mr. Mallock, and consequently leads to a value for the coefficient of terrestrial refraction which is in agreement with observation and with the tables ordinarily employed by navigators for the dip and distance of the sea horizon.

It may be worth while to mention here a very likely source of confusion in comparing the values of the coefficient of terrestrial refraction k found by different observers under different conditions, and especially by observers in different countries. There are two definitions of k in use by surveyors, one of which makes its numerical value double that given by the other. An assistant of mine who read Dr. Hunter's letter was greatly surprised at his statement that $k=0·133$ "is *not* a value ordinarily met with in practice," because in Egypt we ordinarily use $k=0·13$, and our trigonometric levels derived from observations made in the afternoon hours when refraction is at its minimum and steadiest value are found to agree surprisingly well over great distances with those found by spirit-levelling. The explanation of the apparent discrepancy between Dr. Hunter's statement and our experience is that we follow the Continental practice in defining k as the ratio of the curvature of the refracted ray to the curvature of the earth, while Dr. Hunter and most English writers define it as half this quantity.

It does not seem to be very generally known that a rational formula for calculating the coefficient of terrestrial refraction at any point where the barometric pressure, air-temperature, and temperature-gradient are known was advanced by Jordan so long ago as 1876. This formula, which is given, together with an account of the theory on which it rests, in Jordan's "Handbuch der Vermessungskunde," Band 2, is

$$k=0·2325\,\frac{\mathrm{B}}{760}\,\frac{1}{(1+\alpha t)^2}(1-29·39n),$$

where k is the coefficient of terrestrial refraction, defined as being the ratio of the curvature of the ray to that of the earth, B the barometric pressure in mm., α the coefficient of expansion of air at constant pressure, t the air-temperature in degrees C., and n the temperature-gradient in degrees C. per metre of height.

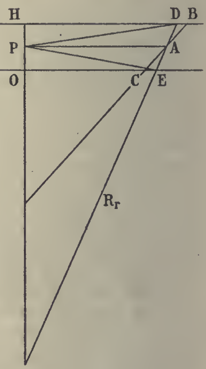

FIG. 1.

Jordan's theory is probably not quite complete, in that it omits any consideration of variations in the humidity of the air; but it does take account of variations of pressure, temperature, and temperature-gradient, and these are probably the principal factors affecting the value of k. The resulting formula is very simple and easy of application, and, so far as I have been able to test it in the Egyptian deserts, I have found it to give results which are in good agreement with those of observation. It appears also to accord very satisfactorily with Indian experience; for when applied in the two examples given by Dr. Hunter in his letter, one at sea-level and the other at an altitude of 19,000 ft., it yields (allowing for the difference in the definition of k) results identical with those which were found by Dr. Hunter to agree well with numerous observations. JOHN BALL.

Survey of Egypt, Cairo, December 14.

IN NATURE of June 9, p. 456, a letter appeared from Mr. A. Mallock giving a proof that the path of a nearly horizontal ray through the earth's atmosphere is a circle of about 14,900 miles' radius, and later (August 11, p. 745) Dr. de Graaff Hunter, of the Indian Survey, wrote controverting Mr. Mallock's statement, and asserting in effect that the radius of

the ray as deduced from measured values of the coefficient of refraction is distinctly higher, being about six and a half times the earth's radius, or about 26,000 miles.

Both letters contain an inadequate presentation of the facts of atmospheric refraction in that they assume that the path of the ray is circular. A very much fuller investigation is necessary in order to account for the distance of the visible horizon or its depression below the true horizontal.

Starting with the assumption that the atmosphere is in static equilibrium, leading to the differential equation $dp = -g\rho dh$, and with the pressure-density-temperature law $p = C\rho T$, a further assumption must be made before a complete solution can be arrived at giving pressure, density, and temperature in terms of height. A simple assumption to make is that of a uniform temperature-gradient expressed as $T/T_0 = 1 - \alpha h$. For the isothermal conditions $\alpha = 0$; for the adiabatic, α corresponds to a drop of 1° C. per 330 ft. increase in height. The integration of the general equation leads, provided h does not exceed 200 or 300 ft., to $p = p_0 - g\rho_0 h$ and $\rho/\rho_0 = 1 - (g\rho_0/p_0 - \alpha)h$. Since by Dale and Gladstone's law ρ is proportional to $n - 1$, we obtain without difficulty

$$n = n_0 - 0{\cdot}00029(g\rho_0/p_0 - \alpha)h.$$

Further, it is not difficult to show that with a ray that is nearly horizontal the radius of curvature σ is given by the approximate equation

$$1/\sigma = 0{\cdot}00029(g\rho_0/p_0 - \alpha).$$

This equation will give any value we like for σ provided we assume a suitable temperature-gradient. If we put $\alpha = 0$ (the isothermal state) we get substantially Mr. Mallock's figure. If we take the adiabatic gradient the radius is about 20,000 miles. If we take a fall of temperature of 1° C. per 200 ft., Dr. de Graaff Hunter's value results. A gradient of 1° C. per 100 ft. gives a flat ray and an atmosphere of uniform density. To obtain greater curvatures than Mr. Mallock's figure the temperature-gradient must be reversed.

It is no use to take this formula and expect it to be uniform over even very narrow levels when close to the surface of the sea. The temperature-gradients in the first 30 ft. (the average height of the bridge of a ship above the sea) are very frequently greater than any of the gradients mentioned above, and show wide variations in that space. In such case the path of a ray from a visible object more than a mile away is nothing like circular, but may have variations in its curvature of 300 or 400 per cent. I am aware that the value of the coefficient of refraction mentioned by Dr. de Graaff Hunter is used in books of nautical tables in computing the dip and distance of the sea horizon, but I am aware also that actual measurements of the dip at sea show that tabulated values are frequently in error, sometimes even of the wrong sign! Measurements made by Blish off the coast of California showed that a zero dip is quite possible. In the Red Sea the sea horizon is often refracted above the true horizontal.

Consider the path of the ray of light from the horizon to the observer's eye when the dip is zero. The path touches the earth's surface at the horizon and touches a concentric sphere of perhaps 30 ft. greater radius at a point only six or eight miles away. The radius of curvature of the ray must be greater than the earth's radius at the horizon and smaller at the observer—a maximum at the first point and a minimum at the second. Neither Mr. Mallock's figures nor Dr. de Graaff Hunter's can deal even approximately with a ray-path of this nature, and I think it may be asserted without question that to take adequate account of the path of rays of light through the lower levels of the atmosphere demands consideration, not only of the curvature of the ray-path, but also of the first and second differentials of the curvature.

Admiralty Research Laboratory, Teddington, Middlesex, December 22.

The Message of Science.

Two great questions are raised in the abridgment given in NATURE of December 22 of the notable address delivered by Sir Richard Gregory during the Edinburgh meeting of the British Association. They are:—(1) How can an interest in, and respect for, science in all its branches, with their essential unity, be developed locally? (2) How can the work of the British Association be so broadened and improved as to ensure that it will yield—to use the words of Sir Richard Gregory—"a statement of ideals and of service, of the strength of knowledge and of responsibility for its use"?

Local scientific societies consist of three types:—(1) Sectional bodies interested in general engineering problems or in the technical details of certain sciences applied to the chief industries of the district. (2) Natural history societies or field clubs. (3) Literary and philosophical societies which provide in a few large towns a good library and series of winter lectures.

With regard to the first type little need be said. They fulfil their specialised functions fairly well, but their work would be greatly improved, and made gradually more attractive, if it were possible to secure an outlook on the broad field of science. Sir Richard Gregory said in the course of his address in Edinburgh: "Whatever Labour may declare officially, it is scarcely too much to say that artisans in general show less active interest in scientific knowledge now than they did fifty years ago." This statement is true, not of artisans only, but of all classes. The demand has been made on science: "Make us rich and comfortable." Science, in a large measure, has responded. But with wealth and comfort has come a lessening of respect for knowledge. The highest things that science can give—an ardour for truth, the power to rise above sordid interests, the desire to become co-workers in an infinite process by which soul is drawn from matter—have been set aside, and we have been landed in a back-wash.

I do not think any revolutionary changes are necessary locally in order to bring back the enthusiasm which linked science a generation ago to human liberty and human justice. Sir Richard Gregory speaks of a federation of local societies "to proclaim the message of knowledge from the housetops." It may be necessary, first of all, for these societies to find out what the real message of knowledge is, but they need not wait for perfect vision; much can be done while they are only groping.

What is wanted, above all things, is such an infusion of earnestness as will arrest the displacing power of the mere lantern lecture. The lantern has been a good servant, but it is threatening to become a bad master. At present the great trouble of the secretary of a literary and philosophical society is to make his organisation pay its way. The chief thing for which the organisation stands is often sacrificed in the attempt to secure popular support. This attitude must be abandoned even if abandonment leads into the wilderness. The message of science will come back from there with renewed constraining power. There are thousands waiting for the message. What

stands in their way is the lack of faith and of courage on the part of the present directing agencies. Probably the most practical suggestion of immediate value that has been made is that the various scientific societies in any town should arrange meetings for study and discussion—the discussion which seeks agreements and does not emphasise differences—and that the underlying, but not obtrusive, object of the meetings should be the progressive connecting of science with individual and corporate conduct.

The second question has many factors in common with the first. The British Association has suffered from the mental reaction which set in a quarter of a century ago. It is a much smaller factor in the thought and life of the age than it was a generation ago. I think the first helpful change desirable is the recognition of a new principle in the selection of a president and in the making of his annual address. Above all things, the president should stand for the unifying of the sciences, and his address should make some definite contribution to that unity, even when it is built largely on the recent achievements of one section of knowledge.

It is only through a conception, becoming ever clearer, of this unity that science can become the "chief formative factor of modern life." The yearly appeal of a president may do much, but more would be achieved if a day were set apart for the study or discussion of the thoughts and facts he has communicated—a study or discussion, I say again, which should emphasise agreements and not differences.

Progress in this direction might receive a healthy impetus from the universities. They, too, have lost a considerable amount of influence. They are not, at home or abroad, leading humanity. The note of real universality is departing from them. Here again the first practical improvement will come from the manifestation of greater care in the selection of the principals of the attached colleges. They ought to be something more than skilled administrators. They, too, have a great unifying function.

This unifying work might be facilitated if there were periodical meetings of the various professors and lecturers for the study of unifying problems. That does not, I admit, promise to help them immediately to overcome the financial difficulties which are now laming them to a terrible extent and driving them to seek greater support from an overburdened State. But if the universities, encouraged by a steadily increasing enthusiasm for science locally and centrally, were themselves to become again great inspirers of thought, they would soon cease to be troubled by the lack of pence.

W. ROBERTSON.

Middlesbrough, December 29.

Cohesion.

THE theory of cohesion put forward by Dr. Herbert Chatley in NATURE of August 18 is logically based on those of other investigators, and, consequently, does not involve any new element. In all these theories cohesion is made to depend on centrally directed forces which follow either the inverse square law of gravitation or electrical attraction, or that of some other inverse power higher than the second. Dr. Chatley says: "It is difficult to conceive of one force having all these properties, but perfectly simple to imagine an attraction and repulsion combined that will do so, provided that *the attraction decreases more slowly with separation than the repulsion.*" He takes the ground that the force of cohesion as stated by him is related to those following the inverse square law, and that the question of the relation between them is of great importance.

Now it is a matter of common observation that two free liquid spheres on coming into contact with each other always coalesce. The force which causes this is evidently a force *enveloping* their masses, and not a force attracting them. This enveloping property of surface tension was noticed by Maxwell and others; but the theory which makes it depend on molecular attraction renders it impossible to conceive of such a force as enveloping *molecular* masses.

The present writer has adduced (*Phil. Mag.*, June, 1921) very strong, if not conclusive, evidence that the same force which causes liquid spheres to coalesce also causes the free molecules of a gas to coalesce or cohere. It cannot, therefore, be explained by molecular attraction. The alternative is that *it is an elemental force acting, not in lines, but over areas.* As such it is a universal property of the surface of both liquid and solid mass extending to molecular dimensions.

Fortunately, however, there is very definite and easily verifiable evidence that cohesion, and adhesion also, is due to a surface force, whatever its nature may be, as can be seen from the following simple experiments which will be published later in fuller detail.

Spheres of mercury, ranging from 0·05 mm. to 1·5 mm. in diameter, were hung from a drop of water wetting a glass surface above. Each one fitted into an inverted hemispherical cavity in the water, with a well-defined angle in the contact circle where the water surface joined the mercury surface. With a specially adapted microscope the diameter of the sphere, the width of the contact circle, and the angle between its water arm and the vertical were measured. From these measurements, W, the weight of the mercury sphere, and T, the vertical component of the pull of the water surface on the mercury, were calculated for a large number of spheres. The results showed that for small spheres T greatly exceeded W, but tended to become equal to W when the spheres were at the point of falling off. The ratio T/W decreased gradually from about 6 to 1, thus showing that the surface force of the water pulling on the mercury in the periphery of the contact area was more than sufficient, except in the limit, to support the weight.

Similarly, mercury spheres, with diameters from 0·05 mm. to 2·25 mm., were suspended from a horizontal glass surface. They were attached to the glass either directly or by suspending them from water as before and allowing the water to evaporate. The mercury surface was joined to the glass surface in the periphery of a wide circular contact area, and formed a definite angle with the glass surface. Measurements were made as before, and W and T (for mercury) were calculated. The results showed that, as the spheres increased throughout the range, the ratio of T/W decreased from the surprisingly large number of more than 6000 to about 2. Had T, however, been calculated from $\sigma=270$ instead of $\sigma=547$, the decrease would have been from about 3000 to 1 as before, and hence 270 may be regarded as an approximate value of the surface tension of glass. The increasing values of T/W for the smaller particles would account for the persistence with which molecules of a gas condense on a glass surface.

Further, small particles of any insoluble solid become attached to any surface above by the evaporation of a connecting water drop; or, if the particles be clean and small, they become attached to any clean surface by simple contact with it. This is amply confirmed by extended observations.

Now there is no reason to think that the force of cohesion is not of the same nature in the case of two solids as it is in the cases of a liquid and a solid and

of two liquids. Moreover, as it has been shown that two free molecules of a gas cohere (coalesce) from this same cause, it is justifiable to conclude that in all cases down to molecular dimensions cohesion is simply *a surface force pulling in the periphery of the contact area perpendicularly to that area.* It may be remarked also that these results furnish no evidence of the so-called molecular attraction.

By calculation this force binding two molecules of water together is $2{\cdot}05 \times 10^{-5}$ dynes; of mercury, $7{\cdot}7 \times 10^{-5}$ dynes. These agree with Dr. Chatley's statement that (molecular) cohesion is of the order of 10^{-6} dynes. Again, in the case of two molecules cohering in this manner the enveloping force can have a range not greater than two molecular diameters, while for larger molecular masses the range may be as great as three or four molecular diameters. It thus fulfils the condition for the range of action. In comparison with their gravitational attraction this force binding two water molecules together is of the order 10^{33} times as great. It is of the same order as the electrical attraction of two oppositely ionised molecules just before they come into contact. It causes a pressure on the interior molecular mass of the same order as the intrinsic pressure of the liquid. It does appear, then, that one force can be conceived as having all the properties of cohesion.

The conception of this force as a cause of molecular phenomena appears to be, in fact, fundamental. It solves the problem of surface tension; it explains, as we have seen, both cohesion and adhesion, and it accounts satisfactorily (*Phil. Mag., ibid.*) for the latent heat of condensation. But besides all this there is the remarkable coincidence that the force itself is located, or performs its function, in the precise area bounding free mass that the phenomena of reflection and refraction of light take place and electrons have their movement. These considerations give point to Dr. Chatley's concluding words: "It would appear that a complete solution of the macroscopic properties of matter would also solve the question of the inner structure of the molecules and atoms."

The Resonance Hypothesis of Audition.

ADDITIONAL evidence in favour of the resonance hypothesis of audition has been found recently.

The study of long-distance telephony has shown that low-pitched notes travel more rapidly than do those of high pitch, owing to the impedance of the electrical circuits. Mixed tones must, therefore, arrive with phase relationships between the high and low tones quite different from those with which they started.

In spite of this, even such complex sounds as those composing human speech are found to suffer but small apparent change in quality and distinctness during transmission. And this statement appears to apply equally to wireless telephony, where similar changes of phase must occur.

These facts suggest that the ear responds to tones quite independently of their relative phases, and therefore that true harmonic analysis must take place in the organ of Corti. A survey of the different types of harmonic analysers used in physics, for tide production and the like, shows that such harmonic analysis is invariably performed by a series of some type of resonator. Presumably, therefore, since the ear can carry out harmonic analysis, it also must contain resonators.

To test the premises more thoroughly the following experiment was carried out:—

Two electrically driven tuning-forks, emitting pure tones, were connected to separate battery and switch circuits, and were mounted on separate tables, so that while they vibrated independently their tones entered the ear of the observer simultaneously. They were tuned so that their tones had rates of vibration in the ratio of 1 and 3, this ratio being chosen because of all pairs of tones these give the largest changes in the form of the sound wave-curve as the relative phases of the tones are changed. Thus with one phase relationship the sound wave-curve has a single sharp, well-marked peak, whereas with another phase relationship two peaks are found, having a trough between them. If, then, the ear is affected at all by the form of the sound wave-curve, these two tones, combined in different relative phases, should show it. The experiment was performed by causing the higher-toned fork to sound continuously, the lower-toned one being turned on and off at irregular intervals, so that the relative phases should be chance ones. No difference whatever in the quality of the sound could, however, be detected by the observer. The response of the ear appeared to be quite independent of the relative phases of the tones, and, therefore, we must conclude that the ear effects a true harmonic analysis by means of resonators.

If the above experiment is repeated with two sources of tones that are not free from overtones it is found that the ear does readily detect differences in the quality of the sound as the relative phases of the tones are altered. For example, if Helmholtz's syren is used with, say, 18 holes operating in the lower wind chest, and 6 holes in the upper, then there are found to be 18 regularly spaced positions where the lower tone predominates, and 18 intermediate positions in which the upper tone predominates.

These effects are produced by the summation and interference between the upper tone and the second harmonic overtone of the lower tone. When holes of both wind chests are exposed simultaneously, summation occurs, and the upper tone predominates, whereas when the holes of one chest alternate with those of the other, interference occurs which weakens the upper tone, so that the lower tone predominates.

Many years ago there was considerable controversy as to whether the ear could, or could not, detect difference of phase. The above experiments suggest that pure tone free from harmonics may have been used by one school, and impure tones containing harmonics by the other, because in this way their difference in opinion could be readily explained.

King's College, Cambridge.

The Action of Sunlight.

IN NATURE of December 15 Sir Oliver Lodge is good enough to refer me to some experiments on the antiseptic action of sunlight which he carried out long ago in association with the late Prof. Marshall Ward. I have not yet been able to see the memoir to which Sir Oliver Lodge refers, but I believe that I am already well acquainted with it, and have been able to quote its essential findings on many occasions in connection with the demand for the abolition of the coal-smoke curse—thanks to an admirable account of Marshall Ward's methods and results, referred to the year 1892, in Sir James Crichton-Browne's "Light and Sanitation," an address delivered in Manchester in 1902 (Sherratt and Hughes, 27 St. Ann Street, Manchester). Particularly I value the last paragraph, in which Sir Oliver Lodge praises the anti-

septic and innocent quality of the sunlight just as we get it after filtration by the "unpolluted atmosphere."

But after seeing the clinical action of sunlight at Leysin under Dr. Rollier and at the Treloar Hospital under Sir Henry Gauvain, and reading the papers of Sonne (*Acta Medica Scandinavica*, vol. 54, fasc. 4, "The Mode of Action of the Universal Light Bath," from the Laboratory of the Finsen Medical Light Institute, Copenhagen) mentioned in my previous letter, I am absolutely certain, as anyone else would be, that there is more in the curative action of sunlight than its bactericidal effect. In a recent lecture before the Physiological Society of University College, entitled "The Physiology and Therapeutics of Sunlight: Facts and Questions," I cited instances and showed photographs of many cases where the value of sunlight could not have depended upon its antiseptic power. Sonne's view is that sunlight warms the blood without appreciably raising the general body-temperature, that this produces the valuable, without the injurious, effects of fever, and that this action is obtainable by the proper use of sunlight, and by that alone.

The practical importance of this fascinating physiological problem is apparent to me after recent visits to certain sanatoria, otherwise admirable, where I have been told that I should see the sunlight employed, and have found, for instance, that open air and diffused daylight, the latter reaching the face and possibly the hands, were regarded as the equivalent of Rollier's treatment; or that the children were scrupulously put under awnings or sent to school in an adjacent wood whenever the sun shone. The pitiful statistics of these places, compared with those of Rollier and Gauvain, point the moral.

Since first drafting this letter I have seen, thanks to Prof. Leonard Hill, new records of work done by Prof. A. F. Hess in New York, showing the cure of experimental rickets in animals fed and continuing to be fed on a diet which invariably produces rickets—when they were placed in sunlight for a few hours daily. No mere antiseptic action is here in question.

With rare exceptions, we do not yet know what heliotherapy consists of in this country; no one yet knows its action, nor even the pure physiology of sunlight. Meanwhile, we are carefully depriving many patients of their one chance of life, and quacks and others are using all manner of artificial lights in therapeutics as if they were equivalent to, or better than, the sunlight, which, according to Sonne's experiments—nicely consorting from another point of view with those of Sir Oliver Lodge—is incomparable.

The Smoke Abatement Committee has now published its admirable Final Report, and reiterates now my plea for an inquiry such as Carrel, I am told, is about to undertake at the Rockefeller Institute in New York, but which no one, not even Prof. Leonard Hill, our great student of the air and temperature relations of the body, is yet making here into the action of sunlight. I believe that the restoration of sunlight to our urban populations, mostly darkened in slums and smoke, is the next great task of hygiene in this country.

C. W. SALEEBY.

Royal Institution, January 2.

Units in Aeronautics.

A LARGE number of equations in aerodynamics appear in the form $R=k\rho SV^2$, where R, ρ, S, V are the reaction, density of the atmosphere, surface, and relative wind velocity.

Since both R and ρSV^2 have the dimensions of force, k is clearly a numerical coefficient unchanged by transformation from one self-consistent system of dynamical units to another, *e.g.* from foot, pound, second, poundal to centimetre, gram, second, dyne.

In transforming to an inconsistent system, k will in general be altered, but the inconsistencies may cancel each other in particular cases so far as to leave k unaltered. For example, if a gravitational unit of force is introduced g times the consistent unit, then we may write $R=k\rho SV^2/g$ pounds *weight* in the British system, or grams *weight* in the c.g.s. system. And while the numerical values of both R and g vary inversely as each other, the value of k is not affected if the system is otherwise consistent.

Prof. Bairstow ("Applied Aerodynamics," p. 119) maintains that the gravitational unit of force is the natural one, and to get rid of the local value of g that mars the consistency of his dynamical equations he introduces a new unit of *mass*, the "slug" of (local) g pounds mass, the use of which he restricts to the measurement of atmospheric density. Then putting $\rho'=\rho/g$ he can write $R=k\rho' SV^2$ in the same form externally as before, and read off the value of R in pounds weight instead of in poundals, all without showing g explicitly.

In this way, in his opinion, "it appears that the divergence of language (*sic*) between science and engineering would disappear."

But if we apply this method of measuring the density of the atmosphere to the estimation of the lift of an aerostat we get, putting m=density of hydrogen/density of air, $(1-m)\ \rho'\times$volume$=$R *slugs weight* ($=g$R pounds weight$=g^2$R poundals!).

Altogether it seems more satisfactory to teach engineers the physical meaning of Newton's laws of motion than to invent units which evade them, just as it has proved better to teach them the elementary notation of the infinitesimal calculus than to devise "calculus-dodging" demonstrations.

A. R. LOW.

London, December 8.

Self-fertilisation in Mollusca.

As the question of self-fertilisation in the more highly organised invertebrates is of considerable importance from the genetic point of view, I would like to direct the attention of readers of NATURE to a publication (Acta Soc. pro Fauna et Flora Fennica, vol. 40, No. 2, 1915), a copy of which I have just received from the author, Dr. A. Luther. It constitutes an important addition to the evidence for the occurrence of self-fertilisation in mollusca, as Dr. Luther states that he succeeded in rearing two generations by self-fertilisation in *Agriolimax agrestis*. I have recently pointed out (Proc. Malac. Soc., vol. 14, 1921) the value of Künkel's work on Arion in this respect; but at the time Dr. Luther's results were not known to me, as the publication was not available and had not figured in the "Zoological Record." Should these important observations be finally confirmed and the technique improved so as to produce more than two generations, a very valuable contribution to genetic study will be achieved. Dr. Luther's work, however, emphasises the necessity for conducting a study of environmental conditions in order to secure improved viability.

I may point out, perhaps, that though quite a number of cases of self-fertilisation have been recorded in Pulmonata by Lang, Holzfuss, and others, the subject is by no means fully explored either with regard to the distribution of the phenomenon among Pulmonata or the circumstances in which it occurs.

G. C. ROBSON.

Cromwell Road, London, S.W.7, December 23.

The Law of the Heart.[1]

By Prof. E. H. Starling, C.M.G., F.R.S.

THE discovery by Harvey of the circulation of the blood, and of the part played by the heart in carrying on this circulation, is one of the few scientific discoveries which have become common knowledge. We have to think of the body as a collection of mechanisms or machines, each one of which is doing some form of work for one common end—*i.e.* the preservation of the body. For this work the oxidation of the food taken in at intervals during the day provides the energy; thus each part of the body must be supplied not only with food derived from the alimentary canal, but also with the oxygen taken in with the air we breathe into the lungs. Like any other machine, each body mechanism produces, as a result of this consumption of the food, waste gases and other waste products which have to be carried to the lungs or to the kidneys and there cleared out of the body. It is for this reason that the existence of the higher animal demands a common fluid, the blood, which can carry food, oxygen or carbonic acid, and is maintained in continual circulation between all the organs of the body, so that the alimentary canal, for instance, may serve for the maintenance of all parts, and the lungs can supply oxygen to these parts or excrete the carbonic acid which is produced as a result of their activity.

But a uniform mechanical circulation would be of little value to the body, since the activities of all its parts vary within wide limits. Thus, during muscular exercise the activity of the muscles may be increased tenfold or more, and this increase means a corresponding augmentation in their call for oxygen and in the quantity of waste products, especially carbonic acid, that they produce. Since the oxygen is carried by the blood, it follows that for the continued functioning of the muscles these must receive a blood supply which is ten times greater during activity than during rest if their activity is not to be brought to an end by a species of suffocation. Therefore, in any violent exercise involving the greater number of the muscles of the body, the circulation must be increased in force seven to ten times, and the heart, which is the pump maintaining the circulation, must under these conditions do from seven to ten times as much work as during rest.

The Mechanism of Adaptation.

What is the mechanism of these adaptations? How is it that the heart is able to carry on a circulation which may vary from a passage of 3 litres of blood per minute up to 30 litres of blood per minute (these figures representing the extreme limits between which the output of the heart-pump may vary according to the condition of the body)? It might be thought that we are dealing here simply with the influence of the central nervous system, which adapts the activity of the muscles of the body to the requirements of the environment, and that the heart being a muscle would be stimulated to contract more strongly at the same time as the nervous system calls into activity the voluntary muscles of the body. There is no doubt that the heart is under the control of the central nervous system, so that its action can be altered, increased, or diminished by the brain in accordance with the needs of the economy, but in the heart we find also a wonderful power of adaptation to the varying requirements of the organism which is quite independent of the central nervous system.

This can be shown quite easily either in the cold-blooded or warm-blooded animal. The heart of the frog and tortoise can be cut out and will continue beating for hours or even days. It has long been known that the heart of the mammal would beat for some minutes after being cut out of the body, but if we take pains to ensure that the muscles constituting the walls of the heart continue to receive their supply of oxygenated blood, the mammalian heart can be made to beat for eight to twelve hours after the death of the animal from which it is taken. In order to investigate this properly we want to make such a preparation that we can control at will all the conditions which may affect the action of the heart—viz. the amount of blood flowing into the heart from the big veins, the resistance which the heart has to overcome when it drives the blood out into the arteries, and the temperature at which the heart contracts. We must be able to measure at any time the output of the heart, the arterial pressure it maintains, its changes in volume during contraction, the pressure in all its cavities during contraction, the amount of blood flowing through the blood vessels of its walls, and its chemical exchanges, as measured by the amount of oxygen which it takes up and the amount of carbonic acid which it produces. It is these chemical changes which give the energy for the work of the heart.

The Heart-Lung Preparation.

All these procedures and controls can be carried out in the heart-lung preparation. In this preparation the pulmonary circulation from right ventricle to left auricle is left intact, and by means of artificial respiration the lungs are blown up rhythmically so that the blood in its course may take up oxygen and get rid of carbonic acid. The whole systemic circulation is replaced by rubber tubes. A glass tube is tied into the largest branch of the aorta, all the other branches being tied, so that the blood driven out by the left ventricle can escape only by the glass tube. From the glass tube a rubber tube passes to a thin rubber tube container within a wide glass tube. This thin rubber tube can be compressed to any desired extent by pumping air at a known pressure into the glass tube

[1] Discourse delivered at the Royal Institution on Friday, May 20, 1921.

surrounding it. We can thus vary at pleasure the resistance which has to be overcome by the left ventricle, and, by maintaining a normal pressure in the beginning of the aorta, ensure a proper supply of oxygenated blood through the coronary arteries to the muscular tissue of the ventricles. It is this fact which makes it possible for the warm-blooded heart to continue to beat for eight to twelve hours after removal from the body. On the other side of the artificial resistance the blood is led through a spiral immersed in warm water to keep the blood at body temperature, and then passes into a reservoir from which a wide rubber tube leads to a glass tube placed in the big vein opening into the right auricle. By means of a screw clip on this tube the inflow of blood may be regulated to any desired extent, and can be kept constant while other conditions are varied. Thus in this preparation the three chief factors, temperature, the inflow of blood, and the resistance to the outflow of blood, can be varied separately and at the will of the operator. Any of the heart cavities or any part of the circuit can be connected to manometers so as to record the pressure of the fluid, and by means of a side tube placed just beyond the artificial resistance we can allow the blood to flow off into a graduated cylinder, and thus measure the time taken by the left ventricle to expel 50 or 100 c.c. of blood, thus measuring the average output of the organ.

An Experiment Described.

A typical experiment may be divided into six stages. Records of one experiment show that in the first stage the heart was beating at a normal rate (72 per minute), the blood pressure varied from 100 mm. Hg, and the output of the heart was 240 c.c. of blood per minute. In the second stage the resistance to the flow of blood through the tubes was increased to such an extent that the pressure rose to 160–180 mm. Hg. The heart continued to beat, and for a time put out just as much blood as it did at the lower pressure. In the third stage the artificial resistance was suddenly reduced to zero, the arterial pressure fell to about 20 mm. Hg, but the heart beat regularly and the outflow of blood was unaltered because the inflow of blood had not been altered. In the fourth stage the inflow of blood was raised suddenly to 600 c.c. per minute. The heart became bigger, but the regularity of its contractions remained unaltered, and it drove forward all the blood that it received.

The same thing happened in the fifth stage, in which the artificial resistance was raised simultaneously with the venous inflow. The reason for these phenomena is that within certain limits the heart isolated from the body can respond to all the demands made upon it; it can overcome a higher resistance, and it can pump out more fluid. In the sixth stage the inflow of blood was further increased to 1200 c.c. per minute, and the artificial resistance was increased until the blood pressure rose to 200 mm. Hg. This was too much for the heart, which began to beat irregularly and dilate widely. It would have failed altogether if the pressure surrounding the thin rubber tube had not then been released to allow the artificial pressure to drop to a level at which the left ventricle could empty itself.

If during this experiment the amount of oxygen taken up by the blood had been measured, and also the amount of carbonic acid given off by this fluid in passing through the lungs, an increase in both these amounts would have been found during the stage at which greater demands were being made on the heart. That is to say, the greater the work done by the heart, the greater the chemical changes to supply energy. A motor-car may be running steadily with an even beat of its engines along a level road; when it comes to a hill it will slow up and finally stop unless the chauffeur increases the chemical changes and the energy of each explosion within the cylinder by opening the throttle and letting in more mixture of petrol and air. In the case of the heart there is no chauffeur, but there is some automatic regulation by which the heart increases its chemical changes, and therefore the energy of each beat, in exact proportion to the work which is demanded of it. It is the nature of this automatic regulation which concerns us now.

The Nature of the Automatic Regulation of the Heart.

By a careful observation of the changes in the heart in the experiment described above we may arrive at some clue to the nature of the pressure, but more accurate methods are necessary if we are to be certain of the correctness of our guess. We must, under these varying conditions, measure: (1) the pressure in the heart cavities produced at each contraction; (2) the volume of the heart cavities—*i.e.* the length of the muscle fibres of their walls. The first we measured in the experiment described by connecting the interior of each cavity in turn with a quickly acting manometer, the excursions of which are registered by an optical method so as to avoid the instrumental vibrations of a lever. The curve of pressure obtained under two conditions—*i.e.* low and high artificial resistance—could then be plotted. It must be remembered that the heart was sending on in each case all the blood that it received, though the work necessary under the high pressure was two or three times as great as that necessary to send on the blood at the low pressure. To measure the volume of the heart the ventricles are enclosed in an instrument known as a cardiometer. This communicates with a piston recorder so that the change of the volume of the ventricles at each beat can be registered on a moving surface.

The question we have to decide is: How does the heart know when it is relaxed that at the next contraction it will have to exert more force than it did previously, when the arterial resistance to be overcome was lower? If we measure the pressure in the ventricles in the manner just described we find that during the period of relaxation of the ventricles the pressure in its cavities is approximately zero, whether the artificial pressure which it has to overcome at its next beat is 50 or 150 mm. Hg. It

is not, therefore, the tension on the walls of the heart which determines the strength of its contraction at its next beat. When, however, we come to measure the volume of the heart, we find that in the isolated heart this is directly proportioned to the work which the heart has to accomplish. Thus we find that the larger the heart—*i.e.* the more it is dilated during diastole—the greater is the pressure that it will get up at the succeeding contraction or systole.

We may put this in another form, as is shown by continuing our experiment over several hours, when we find that the worse the condition of the heart muscle, the more it must dilate in order to get up an adequate pressure. Other things remaining equal, we thus see that the volume of the heart during diastole is a measure of its physiological condition, and we are not surprised that a failing heart means a dilated heart. Of course there is a limit to this power of adaptation. As the heart dilates it is working at an ever-increasing mechanical disadvantage, and a point will finally arrive at which this disadvantage more than counterbalances the physiological effect of dilatation. The heart then dilates widely and fails to empty its contents. Dilatation of the heart means elongation of the muscular fibres composing its walls, so that we may put the law of the heart another way and say that the longer its muscle fibres the greater is the energy developed at each contraction. But in this form this wonderful power of adaptation possessed by the heart becomes part of the general properties of all muscular tissues, since the same rule applies to the fibres composing our voluntary muscles. Can we obtain any more precise and physiological conception of what is involved in this relationship between length of fibre and strength of contraction? Microscopic examination of the fibres, either of the heart or of voluntary muscle, shows that these are composed of innumerable fibrils, so that internally the muscle is made up of structures presenting an enormous extension of longitudinal surfaces. The more the muscle is stretched, the greater will be the extent of these surfaces. A large amount of evidence, based on the electrical and chemical changes occurring in muscle as a result of excitation, points to the contraction as being essentially a surface phenomenon—a molecular change over the whole of the longitudinal surface which may result in a polarisation or depolarisation of the surface and an increase of surface tension, so that the muscle is a surface tension machine in which there is on excitation a direct conversion of chemical into surface energy. The greater the surface the greater will be the number of molecules involved, so that increased length of muscle must increase at the same time the total chemical changes and the total tension produced by the summation of the surface tension of each fibril.

It is only by such a change of molecular dimensions that we can explain the rapidity of events in a muscle (the insect wing muscle can contract and relax 300 times per second), or the high efficiency of the machine, an efficiency which A. V. Hill has shown may amount to 100 per cent. for each isolated contraction, and over a length of time to 50 per cent. As directly measured in the heart-lung preparation, we find a mechanical efficiency of about 25–30 per cent.

Conclusion.

It is impossible here to enter into the applications of this law of the heart, but so far it has not failed in accounting for the behaviour of this organ under all manner of conditions, either in health or disease. It is important to remember, however, that we are dealing here with the isolated heart. In the natural body the mechanisms which we have studied are fenced round, protected and aided by the complex activity of the central nervous system, which is always acting on the heart, balancing its activity against that of the blood vessels, and co-ordinating it with the events which are occurring in every other part of the body. All these factors must be taken into account when we are endeavouring to form a conception of the total behaviour of this organ under the varying activities of the intact animal.

A Summer Visit to Jan Mayen Island.

By J. M. WORDIE.

JAN MAYEN ISLAND lies in 71° N. latitude, 8–9° W. longitude, and is approximately 300 miles north of Iceland, 200 east of Greenland, and 600 west and north-west respectively of Tromsö and Aalesund—the leading hunting ports in Norway. It was possibly discovered in 1607 by Henry Hudson and named "Hudson's Tutches"; the name, nevertheless, by which it is now known commemorates a Dutch seaman, Jan Jacobsz May, who visited the island in 1614. The evidence for the earlier visit by Hudson can scarcely be regarded as trustworthy. May's voyage, on the other hand, is well supported by documentary evidence. Immediately following its discovery, Jan Mayen became frequented almost every year by rival Dutch and British whalers. As a whaling and sealing centre, however, the island was markedly inferior to Spitsbergen. Its importance was, nevertheless, far from small, and the British Government is said to have made a grant of it to the Corporation of Hull in 1618. The number of whalers frequenting the island, however, dropped off very considerably about 1635, the immediate cause being probably a series of bad ice years.

Scoresby was the first to give a scientific account of the island. His narrative was based on a visit in 1817, when he was ashore for a short while and climbed one of the smaller extinct craters. Berna and Vogt in 1861, Mohn in 1877, and Rabot in 1892 also published descriptions. The only expedition last century which remained any length of time on the island, however, was that of the Austrian International Circumpolar Station in 1882–83. During a fourteen months' stay under Wohlgemuth's leadership the party made full magnetic and meteorological records. Their map, which we found very useful and accurate, was the work of von Bobrik. Curiously enough, the natural history was very slightly studied.

Last summer's expedition was originated by J. L. Chaworth-Musters at the beginning of last year; the objects were partly to climb Beerenberg, a mountain more than 8000 ft. high, and often stated to be a still active volcano, partly to complete the Austrian survey of the island by investigating more minutely its geology and natural history. Musters originally intended to charter a hunting sloop from Aalesund. This, however, proved unnecessary through the establishment of friendly relations with a Norwegian engineer, who, under the auspices of the Norwegian Government, was hoping to establish a wireless station for meteorological purposes either last year or this. A satisfactory arrangement was made, and our expedition secured passages in Engineer Ekerold's two ships *Polarfront* (24 tons) and *Isfuglen* (54 tons). On the Norwegian side the affair was now pushed with greater vigour than ever, and after innumerable difficulties Ekerold finally was able to carry his plans into execution.

At Bergen we were met by Prof. Mercanton, of Lausanne, who had long wished to climb the mountain, and it was arranged that on reaching the island he should transfer from the Norwegian party to ours. We were now strongly represented in the various branches of science. Musters himself undertook botanical collections, Bristowe and Lethbridge the natural history, and Mercanton's knowledge of glaciology and mountaineering made him a valuable recruit. The party of six was completed by Richmond Brown as "campman," and myself as geologist. Four of us were members of Cambridge University.

After a somewhat rough passage the island was reached on August 7. It was much too late to think of studying the nesting habits of the birds. It was almost too late to find the plants still in flower. Musters, therefore, accompanied by Bristowe, at once commenced his collecting. The lateness of the

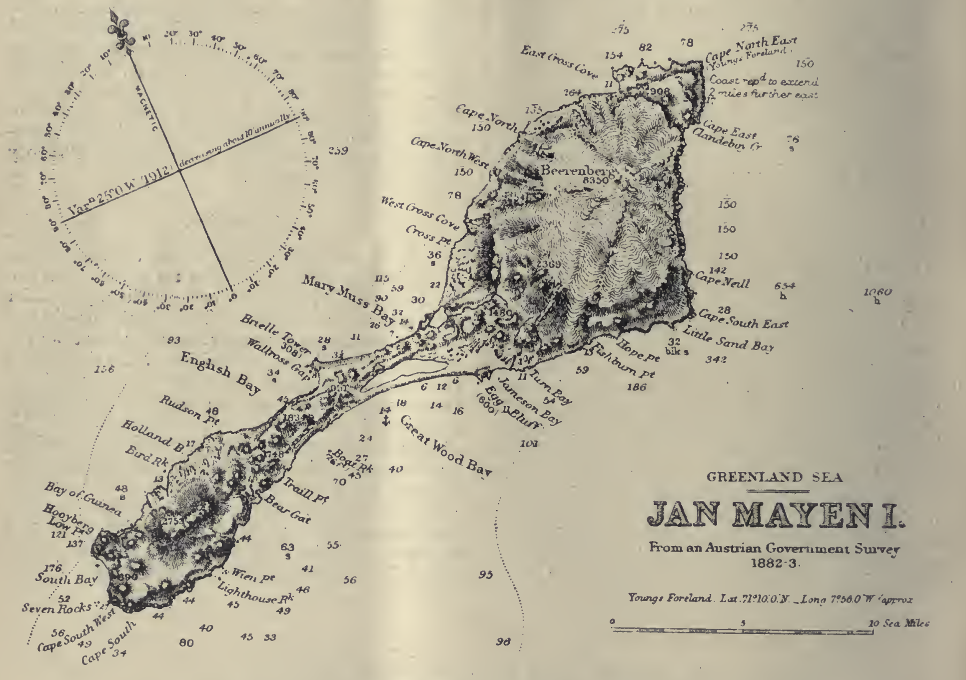

FIG. 1.—Reproduced, by permission of the Hydrographer, from an inset on British Admiralty Chart No. 2751.

season also made it advisable immediately to attack the hitherto unclimbed Beerenberg. To make the ascent direct from sea-level seemed hardly practicable, and an advance camp was, therefore, established at 2700 ft. on the highest of the frontal moraines. Unfortunately, Brown was not well enough to go farther, and the size of the party was thus reduced to three. Starting on August 11 about 11 a.m., for there had been some rain during the night, we trudged for some hours up a gently sloping and but little-crevassed ice-slope to a nunatak at a height of 5600 ft. The real climb now began. Mercanton went first, Lethbridge second, with myself as last man. Two thousand feet of interesting snow- and ice-work brought us finally to the bergschrund not far below the ridge, and after a little delay it was safely negotiated. A stiff climb up a steep snow-wall then brought us to the ridge, and we suddenly found ourselves standing on the rim of a great crater. This was an unexpected and exciting development. The crater was about half-a-mile in diameter, and from 500 to 800 ft. deep. At its northern edge one of the later eruptions had burst the rim and formed a gateway of which the highest part of the mountain is now the western pillar. Since that distant period, however, the crater has become filled with ice, and a much-crevassed glacier now breaks away to the north in a series of striking icefalls, finally reaching the sea (so Mercanton afterwards informed me) as the Weyprecht Glacier. To complete the ascent by following a snow-arête to the actual summit was not long of accomplishment, and gave us a further opportunity of appreciating Mercanton's mountaineering skill. That the summit, deep-covered in rime as it is, has solid rock not far below is certain; scoriaceous lava was collected 50 ft. away. Observations on the summit occupied some time, and, fortunately, there were bursts of sunshine sufficient to enable photographs to be taken. It was almost 9 p.m., therefore, before we commenced the return, but a brisk pace was kept up, and a distance which had taken eight hours on the ascent was now covered in three.

Apart from the geological observations, which showed that the Beerenberg eruptions had been exclusively lava, quite the most interesting and perplexing feature is the gentle ice-slope extending from 5600 ft. down to the camp at 2700 ft. Viewed from a distance, it has all the appearance of an "ice-cap"; it reminded one very closely of the Hardanger Jökul, for instance. At the time I was inclined to regard it as a new type of piedmont or as an "ice-cap" caused by higher precipitation at intermediate levels. It may be so, but, on the other hand, since returning I have noticed that a similar gentle slope characterises both Mount Vesuvius and Mount Erebus, and it can, therefore, be explained on other grounds. Aneroid observations were taken at regular intervals during the ascent. These give Beerenberg a height of 8090 ft. The Austrian figure arrived at by theodolite observations was 8350 ft. It is not usual to prefer aneroid-to theodolite-determined heights, but as the Austrian triangle was a very bad one I think there may be some justification in this case for adopting a lower figure than that generally accepted.

Whilst the mountain was being climbed, Musters and Bristowe had been working at lower levels. After hurried preliminary collections round the base camp they transferred their quarters to a small tent eight miles farther down the coast. From this point the southerly parts were within reach. Musters records a most interesting visit to Seven Hollander Bay, interesting not only historically, but also botanically in respect of the more luxuriant vegetation in that quarter. When Musters finally left the island he was able to tabulate forty-three species of flowering plants, of which five had not previously been recorded there; in addition, the lower orders have still to be worked out and his ecological observations put together. The collections have an added interest just now, as they arrived at the Cambridge Botany School simultaneously with collections made last summer by Prof. Seward in West Greenland, and by Mr. Walton in Spitsbergen. Bristowe's insects are taking longer to name; meantime he has discovered that the spiders are forms met with in the Scottish Highlands; of the flies, etc., only one is native to Britain; the rest are not yet identified. Seventy per cent. of his specimens are new records for the island.

The successful climb on Beerenberg had revealed a good deal about the geology and glaciology. We realised, however, that on that mountain we were dealing with comparatively recent events in the island's history, and the older chapters, if any, had to be discovered. Lethbridge and the present writer in due course relieved Musters and Bristowe at the tent at the south end. From here we ranged over the more distant and inaccessible parts. Apart from the distances which had to be covered, it was arduous travelling both along the coast and on the scree-covered mountain slopes. As the survey was not absolutely exhaustive, additional data may still come to light; meantime the geological record is somewhat as follows: The oldest rocks are coarse and fine augite tuffs; they are generally covered and hidden by later lavas, but are occasionally seen forming rugged and picturesque cliffs along the coast. The earliest lavas were biotite-trachyte; rocks of this composition are nowhere found at craters still well preserved, but always as old hill features. The other and later distinctive lava type is an olivine-augite-basalt rich in alkalis. This rock is found at all the recent craters and also at many older, half-obliterated centres of eruption. A rock of much the same composition, but varying in details, has a widespread occurrence in the form of sills. The south end of the island consists of the older volcanoes; Beerenberg, at the north end, however, must be one of the latest, and round its foot there are many subsidiary cones—*e.g.* Palffy and Vogt craters, which must also be of comparatively recent date. These are exclusively lava craters. One of the very latest, however, is an ash cone—Egg Bluff; it has

a further interest because on the summit there are a few short irregular cracks from which hot steam still issues. Under certain atmospheric conditions these cracks "smoke" quite obviously and this phenomenon was possibly the "eruption" reported by Scoresby in 1818. Scoresby's account is unfortunately written with considerable hesitation. "Smoke" on Egg Bluff scarcely satisfies his description, however. It seems more probable that an ash eruption actually took place at the foot of the western side of Vogt (Scoresby's Esk) crater, possibly in the same spot where the only other authentic eruption, that of 1732, was observed by the whaler, J. J. Laab. Beerenberg itself has never been observed in activity. There is no evidence of when the first eruptions took place; they may even be post-glacial.

Photo] *[W. S. Bristowe*

FIG. 2.—Beerenberg from the south.

As regards glaciology, Prof. Mercanton has supplied me with a brief summary. Glaciers are confined to Beerenberg. Four elements are distinguished: (*a*) the glacier which issues from Beerenberg crater; (*b*) a "collerette glaciaire," continuous in its middle portion, covering the north and north-east parts of the mountain; (*c*) an independent system on the eastern flanks; (*d*) a great "collerette" covering the flanks from north round through west and south to east-south-east. (Part of the latter has already been referred to as the ice-cap feature.) The examination of these different elements shows decreasing glaciation, but whether recent or ancient has not yet been discovered. The rate of movement recorded shows the same order of things as on similar decreasing glaciers in Switzerland. More exact figures, however, will be available when the ground is re-visited.

By the beginning of September it was obvious that the work was now practically complete. Winter weather had already set in, but we were told that we might still make a fair passage. We left the island in *Polarfront* on September 3. *Isfuglen*, however, was remaining another fourteen days in order to bring home the men working at the erection of the wireless station. This they soon completed, and the first message had already reached Norway when we made the coastal waters on September 9. Engineer Ekerold has therefore put up a weather station in a spot where it will be of real value—in the "blind corner" whence no weather warnings had previously been available. He did so

Photo] *[W. S. Bristowe*

FIG. 3.—Mountains at south end of Jan Mayen.

under the most difficult and unsuitable conditions. The work involved the unloading of delicate machines from small boats on an unprotected surf-ridden coast, the overcoming of the difficulties of transport to the site selected, and finally the raising of the masts in adverse wind conditions, and fixing them in frozen ground. Ekerold is now sending daily weather reports to Norway. With the assistance of these it is hoped that it will be possible to forecast the arrival of the northerly and north-westerly gales which come down so suddenly all along the Scandinavian coast, and thus to warn the Norwegian coastal shipping, which has suffered so heavily in the past from the unexpected gales from that "blind corner."

Obituary.

SIR GERMAN SIMS WOODHEAD, K.B.E.

WE regret to record the death of Sir German Sims Woodhead, professor of pathology in the University of Cambridge, which occurred suddenly on December 29. At the commencement of the war Prof. Woodhead was mobilised and became a colonel in the R.A.M.C. (T.), and was for some time head of a camp in Tipperary. He afterwards was appointed inspector of laboratories in the military hospitals in the United Kingdom, a post which involved perpetual travelling and discomfort, the strain of which no doubt conduced to the signs of serious over-work from which of late he suffered. In 1919 he was created K.B.E. in recognition of his valuable war work.

Born in 1855, Woodhead was educated at Huddersfield College, whence he entered the medical faculty of the University of Edinburgh, graduating in 1878. He then spent some time on the Continent, studying in Berlin and Vienna. In 1887 he was appointed superintendent of the research laboratories of the Royal College of Physicians, Edinburgh, resigning this post in 1890 on his appointment as director of the conjoint laboratories of the Royal Colleges of Physicians and Surgeons in London, which he held until his election in 1899 to the chair of pathology in the University of Cambridge in succession to the late Prof. Kanthack. Here it was largely due to his initiative and energy that the new medical school buildings were erected, including the memorial museum to Sir George Humphry.

Woodhead's activities were manifold and untiring; he was a strong supporter of the temperance movement, and was president of both the British Medical Temperance Association and the British Temperance League. He was an hon. LL.D. of Birmingham and Toronto Universities, fellow of Trinity Hall, Cambridge, hon. fellow of the Henry Phipps Institute, Philadelphia, member of the Executive Committee of the Imperial Cancer Research Fund and of the Scottish Universities Committee, and past-president of the Royal Physical Society, Edin. (1878), and of the Royal Microscopical Society (1913–16). It can scarcely be doubted that, had he attempted less, his output of original work in his own special department would have been greater.

Woodhead published in 1883 "Practical Pathology," which reached a fourth edition in 1910; in 1885, "Pathological Mycology" (with Hare); and in 1891, "Bacteria and their Products." He was founder of, and for many years conducted, the *Journal of Pathology and Bacteriology*. In 1894 he published with Dr. Cartwright Wood an investigation on the efficiency of domestic water filters, and during the war devised a method for the chlorination of drinking water. While director of the conjoint laboratories he published a report on diphtheria for the Metropolitan Asylums Board, and devoted much attention to the standardisation of diphtheria antitoxin. Tuberculosis was also a subject to which Woodhead devoted much attention. He drew up a report to the Royal Commission on Tuberculosis in 1895, and was a member of the Royal Commission on Tuberculosis of 1902. Just before the war he devised an apparatus for the continuous record of the temperature of animals, and published the results of investigations obtained by it. Of late the subject of colonies for the tuberculous occupied much of his time, and he was joint author of "Settlements for the Tuberculous." Woodhead was of a genial and kindly disposition, and he will be greatly missed by a large circle of friends and acquaintances.

R. T. H.

PROF. G. S. BRADY, F.R.S.

PROF. GEORGE STEWARDSON BRADY was born in Gateshead on April 18, 1832. His father, Henry Brady, was a surgeon, and he himself was trained for the same career. He was a student of the University of Durham College of Medicine, Newcastle-upon-Tyne, and practised in Sunderland from 1857 to 1906. During the greater part of this period Prof. Brady was also professor of natural history in the University of Durham College of Science, now Armstrong College, Newcastle-upon-Tyne. He began his duties as professor in 1875, and on his retirement in 1906 was elected honorary professor of natural history. In 1906 he went to live in Sheffield, and died there on December 25 last.

Both Prof. Brady and his brother, H. B. Brady, were early interested in natural history, and it is worth remarking that during the time Prof. Brady was studying medicine Tuffen West was an apprentice to his father. All three afterwards attained distinction, Tuffen West as a naturalist artist, H. B. Brady as an eminent authority on Foraminifera, and Prof. Brady for his work on Crustacea, especially on Entomostraca.

Prof. Brady became a member of the Tyneside Naturalists' Field Club in 1849, not long after its inception as a branch of the Natural History Society. He was president in 1871 and again in 1892–93, and he contributed many papers to the Transactions of the Natural History Society. His early papers dealt with algæ and other plant groups, but it was not long before he determined to devote himself to Crustacea and especially to Copepoda and Ostracoda. This work was his hobby, and he devoted his spare time to gathering and to examining his own collections and collections sent to him. The results have been published in a long series of papers, and these brought him into intimate relationship with other workers in the same field here and abroad. But he advanced into a place of prominence when he described the *Challenger* collections of Copepoda and Ostracoda. His reputation was further enhanced when his work on the free and semi-parasitic Copepoda of the British Islands was published by the Ray Society. With the late

Canon Norman he published a monograph of the Ostracoda of the North Atlantic and North-western Europe, and also a catalogue of the Crustacea of Northumberland and Durham.

Prof. Brady's scientific work was done at home. Although he restricted his publications mainly to the results of his examination of Entomostraca from collections made in this and other countries—notably Australia and South Africa—his characteristically neat preparations show that he had interests in all groups which came into the field of his microscope. He was a pioneer in marine dredging, and took an active part in the Northumberland excursions of the early 'sixties, and in the 'nineties he was as keen as before.

It was a pleasure to know Prof. Brady, to be his friend, to watch him work and hear him talk on men and things, on politics and related subjects, and those who had not this privilege will find from his addresses to the Tyneside Naturalists' Club that he gave a critical and well-thought-out consideration to the important questions which arose during his long life and that he had decided opinions and was fearless in expressing them. A. M.

Notes.

We are particularly glad to see the names of Prof. C. S. Sherrington and Prof. W. A. Herdman in the list of New Year honours. Prof. Sherrington, who has been appointed a Knight Grand Cross of the Order of the British Empire (G.B.E.), is the president of the Royal Society, and is to be president of the British Association for the meeting to be held in Hull in September next; and Prof. Herdman, who has received the honour of knighthood, vacated the presidential chair at the Edinburgh meeting last year. The two leading British scientific organisations are thus most appropriately represented in the honours list. Other honours included in the list are:—*Knighthoods:* Prof. G. E. Cory, professor of chemistry, Rhodes University College, Grahamstown; Dr. G. S. Buchanan, Senior Medical Officer Ministry of Health; and Dr. J. H. Parsons, F.R.S. *K.C.I.E.:* Sir John Biles, professor of naval architecture, University of Glasgow. *C.M.G.:* Dr. R. T. Paton, Director-General of Public Health and President of the Board of Health, New South Wales.

This week we begin the publication of a Calendar of Industrial Pioneers, which is intended to supplement the Calendar of Scientific Pioneers which appeared in our columns last year. It is not necessary here to point out the close association that exists between scientific discovery and industrial progress. The two are inseparable. Problems of communication, transport, mining, agriculture, and manufacture depend for their solution on the co-operation of the laboratory and the works. We believe, therefore, that our readers will welcome the series of biographical notes which will recall the great engineers, inventors, manufacturers, and captains of industry who, by the application of the discoveries of the pioneers of science, have extended existing industries, created new ones, or in some other way contributed to the advancement of civilisation.

A conference which commenced on December 12 last was held by permission of the Government at the Ministry of Health, at which delegates from the Health Committee of the League of Nations discussed the international standardisation of therapeutic serums and the sero-diagnosis of syphilis. Prof. Madsen, of Denmark, presided, and Austria, Belgium, France, Germany, Italy, Japan, Poland, Switzerland, Great Britain, and the British Ministry of Health, the War Office, and the Medical Research Council were represented, and the business was conducted by sub-committees. As regards diphtheria and tetanus antitoxins, it was considered both possible and desirable that international units should be fixed for these serums, and a scheme of work to establish them was drawn up. As regards anti-meningococcic, anti-pneumococcic, and anti-dysentery serums, various criticisms were made of the present technique for standardising these, and a scheme of new investigations to obtain more uniformity was adopted. As regards the sero-diagnosis of syphilis, a scheme for comparing the results obtained by the Wassermann reaction with those of other methods was drawn up. An official luncheon was given by the Government to the delegates and guests, at which Sir Alfred Mond presided. It is understood that the conference will meet again in six months' time, probably at the Pasteur Institute, Paris, to report progress and to make further recommendations.

The *Times* of December 24 published a telegram from Delhi announcing that Mrs. Aidie, who is the widow of the late Lt.-Col. Aidie, I.M.S., has discovered a parasite in the salivary glands of the bed-bug, which is probably a stage of the *Leishmania Donovani* parasite of kala-azar. If this important discovery is confirmed it will furnish the final proof of the truth of the theory of Sir Leonard Rogers that the common bed-bug is the carrier of the infection. The human stage of the parasite was first described by Sir William Leishman in 1903, and was found independently by Lt.-Col. Donovan, I.M.S., while in 1904 Rogers cultivated the organism *in vitro* and discovered the flagellate stage of the parasite. In the following year he recorded experiments showing that sterility and a neutral or slightly acid medium, such as he found in the stomach of bed-bugs, were most suitable for this development, while the plan he had advised as early as 1897, of moving healthy coolies out of infected into new lines only a few hundred yards away, had proved so successful in eradicating the disease from tea estates that the infecting agent was not likely to be a flying one, and he pointed out that infection through the ubiquitous bed-bug would explain all the known facts. Major Patton, I.M.S., in Madras next obtained the development of the flagellate stage of the parasite in the

guts of bed-bugs, and certain forms believed to be a post-flagellate stage have since been described by Cornwall, Knowles, and others, but the ultimate development and exact mode of infection have hitherto eluded all workers. Mrs. Aidie has worked for a long time at the Pasteur Institute in Shillong with Major Knowles, I.M.S., so there is every reason to hope that the recent announcement will soon be confirmed. Whether it will help much in dealing with the disease is open to doubt, for long ago Dr. Dodds Price carried out Rogers's suggestion to try to destroy bed-bugs in infected coolie huts in Assam, but without much success, while such very good results in dealing with kala-azar by the tartar emetic treatment are now being obtained in Assam that a vigorous campaign on those lines may be expected practically to stamp out the disease within a few years.

THE following have been elected officers of the third International Congress of the History of Medicine to be held in London on July 17–22 next:—*President of Honour:* Sir Norman Moore, Bart. *President:* Dr. Charles Singer. *Vice-Presidents:* Sir D'Arcy Power and the presidents of the first two congresses, Dr. Tricot-Royer, of Antwerp, and Drs. Jeanselme and Menetrier, of Paris. *Treasurer:* Mr. W. G. Spencer. *General Secretary:* Dr. J. D. Rolleston.

H.S.H. PRINCE ALBERT OF MONACO and Prof. G. O. Sars, of Christiania, were elected foreign members of the Zoological Society of London at its monthly meeting on December 21. The secretary reported that there had been 221 additions to the society's menagerie during November, 104 by presentation, 66 deposited, 5 received in exchange, 44 by purchase, and 2 by birth. The gifts included four lions born in India, presented by the Jam Sahib of Nawanagar. The number of visitors to the gardens during November was nearly seven thousand fewer than during the corresponding month of 1920.

THE annual meeting of the British Medical Association will be held in the University buildings at Glasgow on July 21–28 next. The first three days of the meeting will be taken up by the annual representative meeting, and in the evening of July 25 the new president, Sir William Macewen, will deliver his presidential address. The remaining three days of the meeting will be devoted to scientific and clinical work. Papers and discussions are being arranged for the morning sessions and clinical and laboratory demonstrations for the afternoons. The scientific proceedings of the meeting will be distributed among nineteen sections, each dealing with a particular branch of medicine. In the evening of July 28 a popular lecture will be delivered by Prof. J. Graham Kerr.

AT the next ordinary scientific meeting of the Chemical Society, to be held on January 19, at 8 p.m., Prof. Arthur Smithells will give an account of Langmuir's theory of atomic structure, and will exhibit models. In connection with Sir Ernest Rutherford's lecture on "Artificial Disintegration of Elements," to be given before the Chemical Society on Thursday, February 9, at 8 p.m., it has been decided that visitors will be admitted by ticket only. Fellows of the society will not need tickets for themselves, but those desiring to bring visitors should apply for tickets to the Assistant Secretary, Chemical Society, Burlington House, W.1, not later than January 28. No fellow will be allowed more than two tickets. The lecture will be delivered in the lecture hall of the Institution of Mechanical Engineers, Storey's Gate, S.W.1.

AN exhibition of industrial heating apparatus, to be held in April of this year, is being organised by the Office Central de Chauffe Rationnelle, Paris, under the patronage of the Société d'Encouragement à l'Industrie Nationale and the Société des Ingénieurs Civils de France. The exhibition will comprise apparatus and material connected with "la conservation et la récupération" of heat, and it will be divided into two sections, one including refractory materials, insulators, etc., and the other apparatus and plant, such as economisers, heat-recovery plants, etc. Every facility will be given for experimental demonstrations of exhibits. Further information may be obtained from M. L'Ingénieur Directeur de l'Office Central de Chauffe Rationnelle, 5 Rue Michel-Ange, Paris, XVI. We are informed that the director will be glad to receive applications to exhibit from British manufacturers.

AT a meeting of the Royal Statistical Society on December 20, Mr. E. A. Rusher read a paper dealing with the statistics of industrial morbidity in Great Britain. From a review of investigations on this subject for the past one hundred years, he concludes that (1) age has the greatest influence upon the rate of sickness, and next to this, occupation; (2) occupation has more influence than has either locality or density of population, but the influence of the latter cannot generally be statistically dissociated from that due to occupation; (3) there are no trustworthy statistics in this country of morbidity among female lives; (4) no statistics exist of the sickness experienced by the community at large corresponding to those for mortality published by the Registrar-General. Mr. Rusher advocated a systematic attempt to investigate the data now available through the operations of approved societies under the National Insurance Acts in order to obtain some measure of occupational incidence of sickness analysed into classes of disease.

COL. T. C. HODSON writes in amplification of our condensed report of his remarks in the discussion which took place at the Royal Anthropological Institute on Prof. Elliot Smith's paper on "The Mound-Builders of Dunstable" (see NATURE of December 15 last, p. 512) to point out in reference to the distinct forms of disposal of the dead associated with the mounds, viz. (1) burial of a woman and child in a flexed position and (2) cremation, that in India many living races have two—in one case four—different modes of disposing of the dead, varying according to (*a*) cause of death and (*b*) social status of the dead. Col. Hodson also points out that one of the elemental features of Jhum cultivation in Assam is the use of logs of burnt

trees as retaining walls to hold up the soil and keep in the moisture, and that Mr. Mills's reference to ignorance of the proper ceremonial as a reason alleged for not adopting terrace cultivation throws an interesting light upon the possibilities of the negative aspect of the evidence with regard to this method of cultivation.

In an elaborate paper published in the Journal of the Royal Institute of British Architects (third series, vol. 28, No. 3, October, 1921) Mr. Jay Hambridge supplies "Further Evidence for Dynamic Symmetry in Ancient Architecture." The paper gives a careful series of measurements of the Parthenon and other Greek temples which are of permanent value. The writer remarks: "The temple at Aegina is older than the Parthenon, older than the Zeus building at Olympia; therefore the finding of a persistent dynamic theme in the structure which is simply a variation of the themes at Bassæ, Olympia, and Athens suggests that symmetry schemes had some sort of ritual significance. And this is borne out by the record from India. About the time of the erection of the Greek temples of the best period, if not somewhat earlier, there existed in India specific rules for sacrificial altar construction. These have survived as the Sulvasutra, or 'rules of the cord,' better, 'rules of the rope.' Some authorities date the Sulvasutra about 800 B.C., others place it at 600, 500, 400, and even 200 B.C. The exact date is immaterial, as the point of importance for us is that these rules describe in detail the construction of the root rectangles which constitute the base of classic Greek proportion."

The year which has just closed will long be remembered for its shortage of rainfall over the British Isles, as well as in many other parts of Europe. At Greenwich Observatory, where records are available for more than a hundred years, there is no previous year since 1815 with so small an amount of rain. In 1921 the total measurement for the twelve months was 12·50 in., which compared with the average 24·41 in. for the hundred years from 1816–1915 is only 51 per cent. of the normal, and compared with the normal for thirty-five years, 1881–1915, in use by the Meteorological Office, viz. 23·50 in., is 53 per cent. of the normal. Compared with the one hundred years' normal, the rainfall in each month was less than the average, but compared with the normal for thirty-five years, January and September had slightly more rain than the average. The month with least rainfall was February, with 0·12 in., followed by July with 0·15 in. In the previous 106 years the year of least rainfall was 1864 with 16·38 in., and this is followed by 1847 with 17·61 in., and 1858 with 17·70 in. The rainfall for the eleven months to the end of November was 68 per cent. of the average in England and Wales, 94 per cent. in Scotland, and 86 per cent. in Ireland. At Tenterden, as representative of Kent, the rainfall for the eleven months to the end of November was 49 per cent. of the average; at Arundel, as representative of Sussex, 53 per cent., and at Oxford 59 per cent. Notwithstanding the wild and unsettled character of the weather at the close of the year droughty conditions continued in the south and south-east of England.

The annual report of the Gresham's School, Holt, Natural History Society for 1921 includes a useful list of the flowering plants found in the neighbourhood of Holt, Norfolk, the work of the botanical section, and a preliminary list of the Hemiptera–Heteroptera of the same district, compiled by the entomological section.

In the *Quarterly Journal of Microscopical Science* (vol. 65, part 4), Prof. Champy and Mr. H. M. Carleton discuss the shape of the nucleus and the various mechanical causes, such as surface tension and the pressure of cytoplasmic inclusions, by which it is determined. They come to the conclusion that the amitotic division which occurs in certain highly specialised nuclei results from the attainment by the nucleus of a degree of differentiation that is incompatible with mitosis.

To the few known cases of flagellate protozoa with trichocysts another has been added by the observations of Dr. W. Conrad, who has found trichocysts in *Reckertia sagittifera*, n.g., n.sp., a colourless Chloromoradine found in an aquarium in the Botanic Garden in Brussels (Bull. Acad. Roy. de Belgique, Classe des Sciences, 1920, No. 11). The organism is about 50 microns in length, and has two flagella, one directed anteriorly and the other posteriorly. In addition to swimming by means of the flagella, the organism can creep by means of blunt pseudopodia, about six in number, which serve also for the capture of food, such as bacteria, flagellates, and algal zoospores. A layer of slender, rod-like trichocysts in the ectoplasm gives this region a fine and regular striation. Trichocysts are not present in the pseudopodia. Close to the insertion of the flagella are two lateral contractile vacuoles which contract alternately and discharge their contents into a median apical vacuole. Food vacuoles, similar in their reaction to neutral red to those of Paramecium, are present in the endoplasm. The nucleus is of the vesicular type, and divides by karyokinesis; cell division is, as usual in flagellates, longitudinal.

The story of Lord Howe Island as told by Mr. Allan R. McCulloch in the *Australian Museum Magazine* (vol. 1, No. 2) is a sad one for the naturalist. Situated three hundred miles to the east of Australia, it was uninhabited by man when discovered in 1788, and, having no indigenous mammals or reptiles, was the home of a vast and interesting bird population which, ignorant of the murderous ways of man, knew not how to protect itself from his ravages. One species, *Notornis alba*, unable to fly, quickly became extinct, and, except for one skin in the Vienna Museum and a few stray notes in journals, nothing is known of this interesting bird. The island is a dependency of New South Wales, and in 1879 was declared a reserve in the hope that what then remained of its fauna would be preserved. Success seemed to have rewarded this excellent measure,

but unfortunately rats were accidentally introduced into the island, and the birds' paradise of two years ago has been reduced to a veritable wilderness beyond all hope of recovery. Mr. McCulloch's account of this tragedy is accompanied by excellent photographs and an interesting description of the natural history of the island, with valuable notes on some of the more interesting birds—magpies, woodhens, and mutton-birds.

IN the *Journal of the Federated Malay States Museums* (vol. 10, part 3, June 1921), Major J. C. Moulton publishes the first of a series of articles on Malaysian butterflies, designed to supplement or correct the information of this region given in Seitz's "Macrolepidoptera of the World." The author defines a true Malaysian sub-region as distinct from a wider area, in which a non-Malaysian element is evident, though not necessarily predominant, and defines it as between lat. 10° N., and 10° S., and long. 95° E. and 120° E., thus including the Malay Peninsula, Borneo, Sumatra, and Java, with its adjacent islands. Thirteen new forms and combinations are described. Major Moulton continues the innovations introduced into his earlier papers of printing the sub-specific names in less prominent type than the generic and specific names, and of retaining the author's name for a species even when followed by a sub-specific name. Both courses have since received the approval of the British Association Committee on Zoological Nomenclature. Valuable notes on variations and geographical distribution are given, accompanied by useful keys for the discrimination of species, sub-species, and forms. We may specially note the distinction drawn by the author between "sub-species" and "forms"—the former as geographical races inhabiting separate areas, and the latter as well-defined forms occurring together over a wide range of country.

THE difficult question of the drainage of the Vale of Pewsey, a district now so well known to the aviators of Upavon, is dealt with by Mr. W. D. Varney in the Proceedings of the Geologists' Association, vol. 37, p. 189, 1921. The vale seems to have been excavated originally along the Pewsey anticline of Cretaceous rocks, which provided a line of weakness, by a river flowing eastward from the Cotswolds and escaping southward by the present gap of the Avon, the river that passes through Salisbury to the sea at Christchurch. This stream was beheaded during the growth of the Severn valley, when the other Avon of the district, which flows through Bristol, was working its head backwards and capturing in addition some of the head-waters of the Kennet and the Thames. Mr. Varney's sketch-maps indicate also the recession of the southern coastline and the formation of the Isle of Wight.

IN a lengthy and most instructive article in the *Geographical Review* for October last on the distribution of population Mr. M. Aurousseau directs attention to the fact that three kinds of maps which at present do not exist are much wanted and could be compiled by the geographical survey of countries. The earth-material map would show the following features: Areas of deep drift soils, areas of residual soils, hydrographical information, fuel deposits, and the location and nature of metallic ores and other economic deposits. The power map should show the distribution of the different power resources—wood, wind, water, coal, oil, etc. Finally, the lowlands map would be a topographical map so coloured that the lowlands, even when of small areas as in the case of intermontane deposits, would stand out prominently. Mr. Aurousseau also points out that in taking stock of the world's resources we require to know the expansion ratio of every land—that is to say, the ratio of the extent to which a given area is occupied to the extent to which it may be occupied. He sketches the nature of the geographical survey required in order that this ratio may be obtained.

AN interesting paper on Greek and Roman engineering instruments, read before the Newcomen Society on December 15 last by Mr. R. C. Skyring Walters, illustrates the uses of historical research applied to science. Such research, the product of co-operation between classical scholars and men of science, was also exemplified at a joint meeting of the Textile Institute with the Manchester and District Branch of the Classical Association and Literary and Philosophical Society last November, and it cannot fail to be of great usefulness. In his paper Mr. Walters quotes the description by Vitruvius of the use of the *dioptra, chorabates,* and water levels in surveying by the Greeks and Romans up to about 100 A.D., and he gives sectional drawings showing reconstructions of these instruments, of which no complete example remains. The *groma*, an arrangement of two crossed arms at right angles with suspended plumb lines at the ends, used for setting out straight lines and lines at right angles, is also shown. In the case of the *dioptra* the advanced stage of development in constructive detail which was reached at the time of Hero of Alexandria, is remarkable. The conclusion is that there are many striking points of similarity, not only in the instruments, but also in the methods employed 2000 years ago, with those of the present day.

WE have received an advance copy of a Carnegie Research Memoir published by the Iron and Steel Institute on the constitution of chromium steels by Mr. T. F. Russell. During recent years industrial applications of iron-carbon-chromium alloys have increased, and a paper on this subject, therefore, is welcome. It must be confessed, however, that the present one does not do much to advance our knowledge of chromium steels. The author has confined himself to an examination of a very restricted area of the iron-carbon-chromium ternary system, in which the carbon does not exceed 1 per cent., while the limit of chromium is 12 per cent. It would have been better if he had taken into consideration in the first instance the equilibrium conditions observed in the binary systems iron-carbon, chromium-carbon, and iron-chromium. Without this a scientific interpretation

of the effects observed in the ternary system is impossible. It follows, therefore, that many of the data obtained are as yet purely empirical.

WE learn from the *Times* of December 27 that Major Klein is at work on a three-colour printing process in which the chief innovation is in the taking of the colour records. Instead of the usual light-filters attached to the camera he illuminates the object with light of the desired colour obtained by the well-known method of cutting off with opaque screens the light not wanted in a spectrum produced by suitable spectroscopic apparatus. It seems that he proposes to try the effect of reducing the width of the utilised portions of the spectrum so as to get a nearer approach to monochromatic light, and also the division of the spectrum into more than three parts for four or five, etc., colour processes.

IN the December issue of the Journal of the Society of Chemical Industry Dr. G. C. Clayton contributes an interesting summary of the effect of the war on the heavy chemical industry. The Leblanc soda industry is stated to be obsolete, and many of the by-products formerly obtained by it have now to be prepared by other methods. One of the main products, caustic soda, is now made either from ammonia-soda carbonate or by electrolysis. The two chief electrolytic processes operated in this country are the mercury process, by the Castner-Kellner Co., and the Gibbs diaphragm process, by the United Alkali Co. In the manufacture of chlorine the Weldon and Deacon processes have been displaced by the electrolytic methods. Electrolytic chlorine is produced by the Castner-Kellner, Gibbs, and Hargreaves cells, and is often liquefied. Chlorates are now made only by electrolysis of chlorides.

M. GOMBERG and C. C. Buchler describe in the August number of the Journal of the American Chemical Society the preparation of benzyl ethers of carbohydrates. Glucose, sucrose, dextrin, starch, and cellulose are readily benzylated, and some of the products may be of technical importance from their colloidal and plastic characters.

Our Astronomical Column.

THE EINSTEIN TOWER.—The *Observatory* for December contains an illustrated article on this tower, which has just been erected in the grounds of the Potsdam Astrophysical Observatory. It contains a vertical telescope of 50 cm. aperture and $14\frac{1}{2}$ metres aperture, fed by a cœlostat. There are two spectrographs, one with a plane-grating of $12\frac{1}{2}$ cm. aperture, the other with two large prisms giving a dispersion of two angstroms to 1 mm. The instrument will be chiefly employed to investigate the presence or absence of the Einstein shift, but it is available for general astrophysical work. It is in charge of Dr. E. Freundlich, under the general control of Prof. Einstein, who has now an appointment at Potsdam. Dr. Freundlich hopes to observe next year's eclipse from Christmas Island, with A. Kohlschütter and Dr. Voûte.

CHANGES IN THE CRAB NEBULA.—One of the very useful researches to which the great American telescopes have been applied is the study of changes in the nebulæ, by comparison of photographs taken at intervals of a few years. The changes have been in many cases unexpectedly large, and imply either relative nearness to the solar system or very high internal velocities.

Mr. Lampland had already reported some changes in the Crab Nebula deduced from seventeen photographs taken with the Lowell 40-inch reflector during a period of eight years. Mr. John C. Duncan gives in Proc. Nat. Acad. Sci., June, 1921, the results of a comparison of two photographs taken with the 60-inch reflector at Mount Wilson at an interval of eleven and a half years (1909 and 1921).

Twelve condensations were selected near the outer contour of the nebula, at tolerably equal intervals. Thirteen comparison stars were chosen, one near the centre of the nebula, the others fairly near the selected condensations. The results may be summed up thus: (1) the motions of the condensations are on the average quite three times as great as those of the stars; (2) while the star-motions are at random as regards direction, those of the condensations are systematically outward from the centre, being greatest at the ends of the long axis of the nebula, where they amount to $2''$ in eleven and a half years, implying a linear speed of 25 km./sec. at an assumed distance of one hundred light-years. There is some (not very certain) evidence of a counter-clockwise rotation of the nebula. The mean motion of all the nebular condensations in eleven and a half years is $+0{\cdot}10''$ in R.A., $+0{\cdot}435''$ in Decl., referred to the mean of the stars.

THE ASTROGRAPHIC CATALOGUE.—The publication of this great work was considerably in arrear even before the war, which, naturally, did not tend to improve the situation. It is satisfactory to note that volumes are now appearing in rapid succession.

Mr. H. B. Curlewis, director of Perth Observatory, West Australia, has catalogued the whole of zone $-35°$, the numbers of stars in each quadrant being 6879, 24,753, 22,139, 19,277. The paucity in the first quadrant is explained by its proximity to the South Galactic Pole. The magnitudes are given by letters, A denoting 8·5, B 9·0, and so on; the scale used is that of Chapman and Melotte, and differs from that used in earlier Perth volumes.

Mr. T. P. Bhaskaran has produced vol. 4 of the Hyderabad section, which catalogues the whole of zone $-20°$, the number of stars being 79,590. This volume completes the zone originally allotted to Hyderabad, about half the plates of which had been taken and measured before the death of Mr. Pocock in 1918. The work has been completed on the lines laid down by him. Standard co-ordinates of all stars contained in the Algiers Astr. Gesells. Catalogue are given at the end of the volume.

Señor Leon Herrero, director of San Fernando Observatory, has produced the first half of the catalogue for zone $-3°$ (R.A. 0h. to 12h.). It contains 58,387 stars, and differs from most of the catalogues in containing X_0, Y_0 co-ordinates for all stars, in addition to the measured x, y.

Agriculture at the British Association.

As was to be expected in an important agricultural district such as Edinburgh, the meetings of the Agricultural Section created a good deal of interest, and were well attended throughout the whole of the meeting.

One or two departures from the usual routine have to be noted. Dr. E. J. Russell, of Rothamsted, delivered a popular address to farmers on "Science and Crop Production" on the day before the formal work of the section began. There was a large attendance from the district, including many representative farmers, and the address was much appreciated. A report of Dr. Russell's address has already appeared in NATURE of September 22, p. 116. The second change was that the presidential address, instead of being read at the opening meeting, was circulated amongst the members. At the meeting on Monday, September 12, the president, Mr. C. S. Orwin, gave an abstract of his address, which was followed by a most useful discussion.

The number of papers offered to the committee was almost embarrassingly large; they were grouped, so far as possible, according to subject. On the opening day they dealt mostly with soil problems. Dr. Winifred E. Brenchley spoke on "The Effect of Long-continued Manuring of Grassland," and described the results of experiments which had been carried out at Rothamsted on permanent meadow-land for a period of sixty-six years—long enough to allow a true estimate to be made of the effect of the different fertilisers apart from the influences of season. The effects of complete manuring, one-sided manuring, no manure, and of lime were considered in detail. Dr. W. G. Smith discussed "Methods of Grassland Analyses," and described the results obtained from plots laid down with various grass mixtures in 1914. The plots were analysed annually, and figures were given showing the composition of the plots now as compared with what was laid down.

Dr. W. G. Smith and Dr. A. Lauder gave the results of a soil survey which had been carried out in the Lothians. More than 100 square miles have been surveyed and the vegetation recorded on 6-in. survey maps. Definite relations have been established between the types of vegetation and the productivity of the holdings, and simple methods of improving the grass were described. Dr. Lauder directed attention to the relation between the amount of organic matter and the lime requirement of the soil—a connection which had been noticed by other workers. Mr. M. M. Monie gave an account of a photographic survey of soils which he had carried out in the west of Scotland. His paper was illustrated with an excellent series of lantern-slides, and the method he proposes, while of limited use by itself, should have a useful place in soil-survey work.

Prof. Hendrick dealt with "The Absorption and Retention of Manurial Substances by Granitic Soils." These soils are free from carbonate of lime, have a slightly acid reaction, and a high lime requirement. Notwithstanding these conditions, it was found that, even in very heavy dressings, ammonia was almost completely fixed and an equivalent quantity of nitrates recovered in the drainage. The phosphate was also completely retained. The potash was less firmly held, and in the later periods of the experiment the retention was very slight.

Mr. H. J. Page and Mr. H. G. Thornton contributed an important paper on "The Rapid Fluctuations in Bacterial Numbers and Nitrate Content of Field Soil and their Interrelation."

On Friday the papers dealt largely with dairying problems. Prof. R. A. Berry dealt with the important commercial question of "The Production and Utilisation of Whey." He showed that on a moderate estimate the amount of whey produced annually is worth 337,000*l*. He emphasised the great loss involved under the present methods of disposal, where large quantities are allowed to run to waste, and discussed the possibility of new methods of utilisation. In addition to pig-feeding, the possibility of preparing milk-sugar and whey powders was considered.

Prof. R. H. Leitch described the recent work he had carried out with starters in cheese-making, as well as experiments in the manufacture of rennet, methods of standardising rennet extracts, and some new developments in butter-making. Dr. W. Taylor and Mr. A. D. Husband contributed a note on "The Varying Rates of Secretion of Milk on its Percentage Composition." They come to the conclusion that the interrelationship of volume and composition may be summarised thus:—The percentages of protein, fat, and ash vary inversely, and the percentage of lactose varies directly as the daily volume of milk secreted. Two papers were contributed by Dr. Tocher, one dealing with "The Statistical Analyses of Scottish Milk Records," and another dealing with "The Methods of Determining the Significant Differences of Yield of Milk."

Prof. Hendrick described "A New Scheme for the Determination of Unexhausted Manurial Values," and dealt in particular with the question of cumulative fertility. Dr. Tocher gave the results of experiments on "The Citric Solubility of Manurial Phosphates," and concludes that citric solubility is a worthless test from the agricultural point of view. The only practical tests are:—(1) The total phosphatic content, (2) the degree of fineness of grinding, and (3) freedom from substances of an injurious character to plants.

Mr. J. Alan Murray described some recent experimental work which he had carried out on "The Composition of Ensilage." Mr. Murray dealt with the loss involved in the making of ensilage, and considered that it was a fallacy that farmers can save money by dispensing with root crops and substituting ensilage in the rations of farm animals. He considered that it was not possible to reduce the allowance of concentrated food by substituting ensilage for roots. In the discussion which followed some exception was taken to Mr. Murray's estimates as to the cost of producing ensilage.

The meeting on Monday was devoted to economic questions, and began with the discussion on the president's address, to which reference has already been made. Lord Bledisloe followed with a paper on "Wheat as the Basis of Britain's Food-Supply in Time of War." He pointed out the advantages of potatoes, supplemented by pig-meat, over wheat. Great Britain is self-contained in its potato requirements and an exporter, while under normal conditions she imports four-fifths of her wheat requirements from abroad. The normal production of wheat is preponderantly in the eastern counties of Great Britain (ten counties out of eighty-six provide more than half the total output), while potatoes are grown in every part of the kingdom. Many farmers are wholly unfamiliar with wheat production, and have neither the implements nor the buildings necessary for its production and storage, but every farmer, gardener, and allotment-holder knows how to grow potatoes. Then again, the wheat crop may be wholly lost for human requirements through bad weather or incendiarism. Potatoes, though subject to disease (which can be minimised by spraying), are less vulnerable, as the edible tuber is beneath the ground. Potatoes provide an

immense quantity of starchy food, far exceeding wheat in output per acre, and the crop can be obtained in shorter time and harvested at different periods of spring, summer, and autumn. Potatoes are, however, relatively deficient in fat and protein, but these can be supplied, by way of supplement, by pig-meat. The production of pigs in war-time should, therefore, be encouraged, and not discouraged as during the late war; their capacity for rapid reproduction, large families, high percentage of fat-yield, and great variety of food products render them invaluable meat-providers in a national emergency. Grazing varieties deserve special encouragement. Another reason for the encouragement of potato-growing lies in the large areas of permanent and temporary pasture, valuable storehouses of accumulated fertility, which can be utilised in time of war when fertilisers are bound to be scarce; no crop thrives better in newly-turned pasture than potatoes. Potato-flour is also useful, for it can be converted into wholesome and palatable bread, scones, and cakes, while surplus or unsuitable potatoes can be utilised both as stock food and as the source of motor spirit, commercial starch, etc. The home production of breadstuffs in the form of potatoes will reduce to a minimum the costs and risks of marine transport, and their production in every part of the kingdom for local needs will largely reduce the strain on internal transport.

In the discussion which followed some doubt was expressed as to whether it would be wise to rely so exclusively on one crop as a source of food, especially in view of the danger of the total failure of the crop by disease.

Sir Henry Rew communicated a paper on "Agricultural Statistics: Their Collection and Use" (Journal of the Ministry of Agriculture, vol. 28, p. 636, 1921); Mr. A. W. Ashby dealt with "Standards of Production in Agriculture," and Mr. Pryse Howell with "Economic Surveys of Agriculture in Wales."

On Tuesday the papers contributed dealt mostly with nutrition problems. Dr. W. E. Elliot and Mr. Arthur Crichton contributed a paper describing a series of feeding and metabolic experiments which had been conducted on pigs with the object of determining the cause of a disease variously known as "rheumatism," "cramp," or "rickets." They conclude from the results of their experiments that the condition is produced in animals deprived of access to earth or other mixtures of minerals, and fed only on grains and certain other concentrates commonly used in pig-feeding. The inorganic constituents in these feeding-stuffs do not correspond with the requirements of the growing pig, for there is a marked deficiency of calcium and an excess of acid radicles. If the mineral matter of a ration composed of these feeding-stuffs be adjusted to the requirements of the animal by a mixture of salts compounded to correct the deficiences the disease does not occur. The addition of fat soluble A or of water soluble C to a ration that produces the condition does not prevent the onset of the symptoms. Mr. John Golding exhibited photographs of a litter of pigs from a sow which was fed on a diet deficient in vitamins; they all suffered from serious malformation of the hindquarters. In the discussion which followed exception was taken to the conclusions arrived at by Dr. Elliot and Mr. Crichton. and it was considered by some speakers that it had not been proved that the disease in question was solely due to a deficiency in mineral matter in the ration.

Dr. J. B. Orr then gave an account of "The Application of an Indirect Method of Calorimetry to the Ruminant," and described the apparatus as adapted for experiments with goats.

Major C. C. Hirst gave a paper on "The Genetics of Egg-production in Poultry." Major Hirst described the results of five years' experimental breeding on Mendelian lines, and showed that the first year's egg-production of a hen depends on the combined action of at least seven main genetic factors. The economic significance of the results was discussed in detail, and the effects of the old methods of grading by winter and annual records were pointed out. The new system of grading production has a double value to the practical breeder, because the descriptive somatic gradings, being based on the genetic factors concerned, give a line also to the breeding value of the bird, for the extreme grades tend to breed true. The adoption of this grading system for laying competitions would lead to rapid progress in poultry-breeding, and be of educational value to poultry-keepers in general, for the winning birds would breed winners with more frequency than they do now.

Miss Dorothy J. Jackson described an investigation which she had carried out in the genus Sitones with the object of investigating which species were injurious to leguminous crops in Britain; the life-history of these species has also been determined. No satisfactory method of control is at present known. In the case of the species which breed on clover control would be extremely difficult on account of their prolonged period of egg-laying, but this difficulty would not apply to the species which breed upon peas and beans. Laboratory experiments on infection with the various fungus spores of *Botrytis bassiana* (*Balsamo*), Montagne, have proved successful, death invariably occurring in from nine to thirteenth days.

In a paper by Miss M. S. G. Breeze "The Degeneration in Anthers of Potato" was discussed. Two definite types of degeneration have been observed:—(1) Where the pollen-grains are formed, but degenerate at various stages of development, and (2) in which the pollen mother-cells are apparently normal, but no reduction division takes place. The question of the inheritance of degenerate condition of anthers was also discussed.

In addition to the formal meetings a visit was paid to the Station for Research in Animal Breeding, where a demonstration on the wools of primitive breeds of sheep was given by Dr. F. A. E. Crew. Dr. R. Stewart MacDougall had an interesting exhibit of insects injurious to stock, while in the library of the Agricultural Department there was an exhibition of early works dealing with agriculture and kindred subjects.

On the Friday afternoon the new Plant-Breeding Station at East Craigs, Corstorphine, was inspected. The party was received by Dr. C. M. Douglas, of Auchlochan, chairman of the committee, and Mr. Drummond described the work of the station. Afterwards the farm of Mr. John Cowper at Gogar Mains was visited.

On the Saturday a whole-day excursion took place to typical farms in East Lothian. The concluding visits were to the well-known farms of East Barns and Barneyhill, where the party was received by Sir Harry and Lady Hope.

If a word of criticism may be indulged in, attention might be directed to the fact that few of the readers of papers seriously tried to confine themselves to the time allotted to them in the programme or made a real endeavour to prepare an abstract of their work suitable for presentation to the meeting. In this way the amount of time available for discussion was much too short. The number of papers accepted was probably rather large, but much time would have been saved had some of the readers appreciated the fact that the time at their disposal was necessarily very limited.

A. LAUDER.

The Megalithic Monuments of Malta.

AT a meeting of the Royal Anthropological Institute held on November 15 last Miss M. A. Murray gave an account of her recent excavations in Malta. The excavations were carried out with the consent and kind help of Prof. Zammit. Three sites were explored, all three being in the south-east of the island. The first excavation was of a mound called Santa Sfia, near the village of Hal Far; this proved to be a megalithic site re-used later, and yielded no result. The second excavation was at Santa Maria tal Bakkari, about half a mile away. Here the remains of a double edifice, locally supposed to be two churches, were found. But various indications, amongst others a torba floor, suggest that the building was pre-Christian, and the form and position of many of the stones show that it was originally a megalithic structure. The supposed dedication of the double building to Santa Maria and Santa Katerina may indicate that the shrine was dedicated to two goddesses, and may therefore throw some light on the early deities of Malta. The name of St. Mary is too universal to be any guide, but as St. Katherine has taken the place of a goddess of beacons and lighthouses, we may have here a sanctuary of that divinity. The position of the shrine lends itself to this conjecture, as it stands on high ground in a direct line with a tiny creek, now unused, but sufficiently large for the small fishing-boats of Neolithic times. The name Tal Bakkari is probably connected with the Arabic Fagr, "dawn, daybreak"; the name "St. Mary (or the goddess) of the daybreak" would be appropriate for a shrine built on a hill, from which the open sea due eastward across the Bay of Marsa Scirocco is clearly visible. The first rays of the rising sun strike directly on the shrine.

The third excavation was at Borg en Nadur, close to St. George's Bay. A group of megaliths have always been a well-known feature of the site; this group consists of two dolmenic structures and a building which now appears to be a semi-circular apse, like the apses at Tarxien and the other Maltese temples. In the short time that could be devoted to this excavation it was possible only to prove that the building extended over a wide area, and may possibly be a double temple like those already known. Behind the uncovered apse and on a level with its highest stones is a field, terraced up to its present height in the usual way by a wall of stones. The axis of the "temple" runs directly into this field, and it is very probable that the whole building remains intact hidden under the soil, as was the case at Tarxien. Excavations in the field in which the uncovered apse stands showed a megalithic building extending more than a hundred feet northward from the apse, and a broken bætyl was found *in situ*. Time did not permit of more than a cursory examination of this portion of the site, and it is still uncertain how far or in what way this building is connected with the apse. South-eastward from the apse is another dolmenic structure built into the wall of the field, and adjoining it in the field behind is an apse filled in and covered with stones, but retaining the characteristic semi-circular form. Excavations on the site will be continued next year.

In the course of the discussion which followed the paper Sir Arthur Evans said that, taking the megalithic monuments in Malta as a whole, it was clear that they belonged to a western Mediterranean province which included Sardinia, the Balearics, and possibly the African side. In the Bronze age the evidence was clear; the implements fitted on to the Spanish group. In Spain are found small segmented beads of faience which were a stage in similar forms found in Scotland and parts of England, and began in Egypt with the XVIIIth Dynasty, and appeared in Crete at about the same time. Possibly they were diffused by the Cretans. Although the segmented beads had not been found in Malta, an imitation, associated with them in Spain, had been found there, and it was probable that the segmented beads would also be found. The Neolithic ornament showed a regular progression, starting from Hagia Kim, but it appeared at so advanced a stage that it could not have originated there, and was, possibly, to be derived from Egypt. A vase from Kamares showed strong affinities with a vase from the Neolithic chambers of Malta. The deduction was that the later stage of this culture in Malta came down to about 1600 B.C.

Mr. Peake referred to the rapid development which had taken place in our knowledge of the prehistory of Malta. In 1913 nothing was known of the Bronze age, but the knowledge of an independent type of pottery had now been developed. The evidence pointed to 1800 B.C. as a possible date for Hal Tarxien. The culture was identical with that found all over the megalithic area. The pottery, for instance, was common to Taranto, Spain, Brittany, Guernsey, Arran, Scandinavia, and also Algiers. The only locality outside the megalithic area in which it occurred was Sicily, where, however, a double spiral stone occurred, similar to one from Hal Tarxien, showing that it belonged to the same order. In connection with his suggestion that this culture came from the East, it was interesting to note that Prof. Zammit had also suggested a connection between Malta and the Persian Gulf.

Graft-Hybrids.

AMONG the departures in procedure which marked the Edinburgh meeting of the British Association was the prominence given to a botanic lecture which aimed at a scientific, but non-academic, account by Prof. Weiss of "Graft-Hybrids." Grafting had been a horticultural practice from very ancient times, and was said to date from that of the Phœnicians, and was certainly practised by the Romans, who believed that the stock exercised considerable influence over the scion.

The question of the production of hybrids by grafting first came to the notice of scientific observers in connection with the *Bizzaria orange*, raised in Florence in 1664, and described in the second volume of the Philosophical Transactions of the Royal Society of London. In this case an orange grafted on a lemon stock bore a large variety of fruits, some resembling oranges, some lemons, while others were intermediate in shape and colour. The most curious combination appeared to consist of an orange shell with lemon pulp. This latter feature was significant in relation to the "graft-hybrids" afterwards obtained, probably the best known and most frequently discussed of which is *Cytisus Adami*, obtained in Paris in 1825 by grafting a small purple-flowered *Cytisus purpureus* on an ordinary yellow laburnum. The graft did not succeed, but from a small bud arising close to the place of insertion a branch was produced inter-

mediate in character between scion and stock. The graft-hybrid is generally sterile, and therefore is usually kept going by grafting. On the rare occasions when seed is set it produces normal yellow laburnum.

In the account given by McFarlane in the Transactions of the Royal Society of Edinburgh for 1892 the suggestion was made that the distribution of characters is such that the graft-hybrid consists apparently of a core of laburnum wrapped in a skin of Cytisus. This supposition has been confirmed in the more recent production of graft-hybrids by grafting common nightshade on the stem of a tomato and *vice versa*. In all cases the stock would appear to furnish the core and the scion the epidermal tissues of the "hybrid."

This simple explanation, however, does not appear to cover fully the graft-hybrids between medlar and hawthorn obtained by Prof. Daniel, in one case of which, at any rate, tissues were present which differed from those of either parent.

In general, therefore, graft-hybrids represent shoots produced adventitiously near the point of grafting and containing representation of the tissues of both plants, in many cases, *e.g. Cytisus Adami*, so arranged that the external tissues resembled those of the scion and the internal those of the stock. There were, however, instances—*e.g.* quince and pear—in which an intimate mixture of the characters of stock and scion appeared in the graft-hybrid which *may* have been accompanied by vegetative union of the cells, but no clear case of this cytological process had yet been established.

The whole phenomenon of graft-hybrids requires further investigation, particularly in relation to cases in which the "hybrid" is said to occur on the scion far removed from the point of grafting, which may turn out to be instances of bud variation, possibly with reversion.

Fauna of African Lakes.

DR. W. A. CUNNINGTON, leader of the third Tanganyika Expedition (1904–5), has contributed to the Proceedings of the Zoological Society of London (December, 1920), a comparative study of the fauna of the African lakes—Tanganyika, Victoria Nyanza, Nyasa, Albert Nyanza, Edward Nyanza, and Kivu, with special reference to the first-named. The results of recent investigation, admirably summarised in this memoir, lend no support to the view put forward in 1898 by Mr. J. E. S. Moore, leader of the first and second expeditions, that Tanganyika represents an old Jurassic sea, and that its fauna is of relict nature. Of the six lakes, Tanganyika has by far the most remarkable fauna—of its 402 species 293 are endemic, and 57 of its 168 genera are peculiar to its waters; of the 146 species of fishes 121 are endemic, and a notable feature is the high degree of specialisation of the Cichlidæ, the lake presenting the richest known assemblage of this family. There is a large molluscan fauna, and of the species of gastropods more than two-thirds—the halolimnic forms (Moore)—exhibit a marine-like appearance, and these are, without exception, endemic. Noteworthy is the absence of Cladocera, and the relative scarcity of rotifers, which may be correlated with the salinity of the water, and especially with the excess of magnesium salts. Dr. Cunnington points out that geological investigation indicates that the extensive beds of sandstone and conglomerate which occur in the lake regions were probably formed under fresh-water and terrestrial conditions, that the trough in which Tanganyika lies was apparently not formed until middle tertiary times, and that the lake had no outlet until recent geological times. Experts have not accepted Moore's comparison of shells from the lake with marine fossil shells of Jurassic age, or his views as to the primitive nature of the halolimnic gastropods. The endemic species in the fauna of Tanganyika are now held to be specialised rather than primitive. The conclusion reached is that Tanganyika owes its remarkable fauna to a long period of isolation, sufficiently extensive for the inhabitants of the lake to assume the characters of species and even genera distinct from those of the neighbouring parts of the continent.

University and Educational Intelligence.

IN connection with the Conference of Educational Associations which is being held at University College, Gower Street, W.C.1, the annual general meeting of the Education Guild of Great Britain and Ireland took place on December 30. The president of the guild, Sir Wilmot Herringham, delivered the presidential address, taking university education as his topic. He commented on the lack of interest in university education shown by the majority of people, and emphasised the value of the inclusion of natural sciences in a general education as a training in inductive reasoning. There is also material gain by the training of a number of skilled practitioners in chemistry, physics, engineering, medicine, etc., but the most important function of the university is discovery. Taking examples from medical science only, gas gangrene, surgical shock, and the effects of poison gas were mentioned as specific problems arising during the war in which investigations were undertaken with success in university laboratories. Another interesting fact mentioned was that between 1838 and 1851 out of every million people born in Great Britain 500,000 died before the age of forty-five years; in 1881 that age had risen to forty-eight; and by 1891 it was fifty-two years—an increase in average life due, at any rate in part, to research and discovery accomplished by men of science working in the laboratories of our universities.

ACCORDING to the December issue of the *School Science Review*, the representatives of the Science Masters' Association met the Joint Standing Committee of the Headmasters' Conference and Association of Preparatory Schools in June last and made certain suggestions for the teaching of science in preparatory schools. As a result it was recommended that (1) in the Common Entrance Examination the scope of the geography paper be widened, that some of the questions in the mathematical paper should test a boy's knowledge of practical mathematics, and that in the composition paper candidates should have an opportunity of showing a knowledge of natural science; (2) candidates for scholarships should be given an opportunity of answering questions on natural science in a *viva voce* examination as well as in the general paper; and (3) at least one, and if possible two, periods a week should be devoted in preparatory schools to science. The council of the Association of Preparatory Schools was at first unwilling to adopt any of these proposals, but after they had been approved by the Headmasters' Conference the council of the Association of Preparatory Schools agreed to them by 12 votes to 3. When this decision is carried into effect boys in preparatory schools will have an opportunity of gaining some knowledge of science at an age when all natural phenomena are of absorbing interest to them—a privilege boys in secondary schools have enjoyed for some time.

Calendar of Industrial Pioneers.

January 1, 1890. Horatio Allen died.—A pioneer among American locomotive engineers, Allen visited the Stockton and Darlington Railway in 1828, and afterwards conveyed to the United States the locomotive "The Stourbridge Lion." In 1871–73 he served as president of the American Society of Civil Engineers.

January 2, 1875. Eber Brock Ward died.—In 1864 Ward erected an experimental steel plant at Wyandotte, Michigan, where the first Bessemer steel made in the United States was produced. He was among the earliest to erect a works laboratory and to employ a works chemist. He also did important work in connection with water and rail transport.

January 3, 1795. Josiah Wedgwood died.—The friend of Watt, Erasmus Darwin, and Priestley, and a fellow of the Royal Society, Wedgwood by his experiments added several new species of pottery ware to English manufacture and turned the current of importation of the finer earthenwares into that of exportation. "He was the most successful and original potter the world has ever seen."

January 5, 1887. Sir Francis Bolton died.—The inventor of a system of signalling for the Army and Navy, Bolton was widely known for his electrical work, and he took a prominent part in founding the Society of Telegraph Engineers and Electricians, now the Institution of Electrical Engineers.

January 6, 1911. Sir John Aird died.—For sixty years Aird was engaged on important engineering schemes, his crowning work being the famous Assuan dam on the Nile built for the Egyptian Government in 1898–1902. The dam is 2200 yards long, it has 180 sluice-gates, and contains more than 1,000,000 tons of masonry.

January 6, 1886. Alhémar Jean Claude Barré de Saint Venant died.—Engaged for many years on practical work as an *ingénieur des ponts et chaussées,* Saint Venant was an eminent elastician, contributing much to the study of the strength of structures.

January 8, 1861. Samuel Clegg died.—A pupil of Dalton, Clegg while an apprentice at Birmingham witnessed Murdoch's experiments on gas lighting and himself became one of the pioneers of the gas industry.

January 8, 1825. Eli Whitney died.—Holding a pre-eminent place among the early inventors of America, Whitney, though originally a blacksmith, graduated at Yale, and while a private tutor in 1793 produced his cotton gin. This enabled one man to clean a thousand pounds of cotton a day instead of five or six pounds. In twelve years the export of cotton rose from 189,000 lb. to 4,000,000 lb. per annum.

January 9, 1843. William Hedley died.—With Trevithick, Stephenson, Blenkinsop, and Hackworth, Hedley was one of the pioneers of the locomotive. In 1813 at Wylam Colliery, near Newcastle, he built the "Puffing Billy," the first practical and efficient locomotive ever constructed. This engine is now in the Science Museum at South Kensington.

January 9, 1862. Samuel Colt died.—In 1835, at the age of twenty, Colt patented his repeating pistol or revolver, for the manufacture of which he built a factory where automatic and semi-automatic machinery was used.

January 11, 1877. Alfred Smee died.—Surgeon to the Bank of England, Smee was best known for his work on electricity. The Smee battery was devised by him, and he did pioneering work in electric metallurgy, including the art of electrotyping. E. C. S.

Societies and Academies.

PARIS.

Academy of Sciences, December 19, 1921.—M. Georges Lemoine in the chair.—The president announced the death of M. Henry Parenty, correspondant for the section of mechanics.—E. **Borel**: The theory of games of chance and integral equations with symmetrical nucleus.—P. **Termier** and L. **Joleaud**: Summary of our knowledge of the Suzette layer (exact age, constitution, and extent): the question of its origin. This layer came from the Alps in the Aquitanian period, and is exclusively formed of Triassic elements.—C. **Richet**: The psychological unity of time.—G. **Gouy**: The surface tension of electrified electrolytes. In a recent communication M. Félix Michaud has proved that the surface tension of an electrolyte is not changed by the electrification of the surface, and hence raises an objection to the ionic hypothesis, since the ions, by accumulating at the electrified surface, should modify the capillary forces. The author states that it is not the ionic theory that is at fault, but the view that the charge is constituted by the ions accumulated at the surface. The latter hypothesis is inadmissible, since a small charge does not diminish the osmotic pressure in the interior of the electrolyte nor the total number of ions per unit of volume.—G. **Friedel** and L. **Royer**: Mixtures of anisotropic liquids and the identity of the stratified liquids of Grandjean with liquids of the azoxyphenetol type.—R. **Lagrange**: The absolute differential calculus.—J. **Wolff**: The series $\sum \frac{A_k}{z-a_k}$.—A. **Denjoy**: Quasi-analytical functions with real variable.—E. **Delassus**: Closed articulated chains.—H. **Abraham** and R. **Planiol**: An astronomical chronograph of precision. An auxiliary electrical clock, controlled by an astronomical clock, beats tenths and twentieths of a second, and these are marked on a smoked strip by a recording galvanometer; the same instrument records the observed times on the same strip, and an accuracy of 0·01 sec. (or greater if required) is readily attained by a direct reading without a micrometer.—J. P. **Lagrula**: The principle and scheme of a recording chronograph with geometrical synchronisation.—J. **Guillaume**: Observations of the sun made at the Lyons Observatory during the third quarter of 1921. Ninety days' observations are summarised in three tables, showing the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude.—E. **Esclangon**: The relativity of time.—J. **Le Roux**: Interference and reflection in a mobile system.—J. **Chappuis** and M. **Hubert-Desprez**: Electrolysis by stray currents. Two metal plates forming the electrodes were placed in sawdust or earth moistened with an electrolyte contained in a wooden box. The course of the corrosion was followed continuously by X-ray photographs.—M. **Taffin**: The measurement of double refraction in tempered glass.—M. **Siegbahn**: New measurements of precision in the X-ray spectrum. A description of an improved instrument of a type described in 1918, capable of measuring a wave-length with an accuracy of 0·002 per cent.—A. **Sellerio**: Analogies and differences between the total galvanomagnetic effect and its correlative thermomagnetic effect.—J. **Duclaux**: The mechanism of continuous-light radiation.—B. **Bogitch**: The expansions of some refractory materials at high temperatures. Refractory bricks of silica, bauxite, clay, chromite, and magnesia and their expansions were studied up to 1500° C. Bauxite bricks had the lowest coefficient of expansion. Silica gave an irregular curve and lost

its strength at about 600° C. The highest expansions were shown by magnesia and chromite bricks, and hence these are suitable only for furnaces in continuous work.—A. **Charriou**: The lime carried down by ferric hydroxide precipitates. To reduce the amount of lime adsorbed by precipitated ferric hydroxide to a minimum the calcium chloride solution should be very dilute and the ammonia added only just sufficient to precipitate the iron.—M. **Grandmougin**: The halogen derivatives of indigo.—J. B. **Senderens** and J. **Aboulenc**: The catalytic hydrogenation of the polyphenols in the wet way. Hydroquinone, resorcinol, pyrocatechol, pyrogallol, and phloroglucinol can be reduced in the presence of nickel by hydrogen under pressure (30 to 50 atmospheres) at temperatures between 115° C. and 145° C. At higher temperatures secondary reactions take place; thus resorcinol at 120° C. gives resorcite (1 : 3-*cyclo*hexanediol), but at 180° C. some *cyclo*-hexanol is produced.—M. **Lespieau**: Derivatives of erythritol-acetylene,

$$CH_2(OH)\cdot CH(OH)\cdot C\equiv C\cdot CH(OH)\cdot CH_2(OH).$$

—R. **Fosse**: The synthesis of a nitrogenous principle of plants, hydrocyanic acid, by the oxidation of ammonia and carbohydrates, glycerol, or formaldehyde. Potassium (or calcium) permanganate, in presence of silver nitrate, with ammonia and various organic bodies, gives cyanides as one of the oxidation products. —C. **Jacob** and M. **Removille**: A fall of meteorites in Cochin China.—P. **Viennot**: The southern edge of the north Pyrenean Flysch, between the valleys of Aspe and Saison.—J. **Yung**: The Hercynian tectonic of the Vosges.—P. **Corbin**: New observations on the eastern border of the mountains of Lans.—Mlle. J. **Pfender**: The presence of pebbles not of local origin at Alon (Var).—E. **de Martonne**: Erosion platforms of the metalliferous mountains of Banat.—Mlle. Yvonne Boisse **de Black**: Researches on the Mindelian alluvium in the high valley of Cère and on the plateau of Lacapelle-Barrez (Cantal).—P. **Loisel** and R. **Castelnau**: The radio-activity of the waters from Mont-Dore. Determinations of the radio-activity of the water from twelve hot springs are given; the gases from eight springs have also been examined. The gases contain a higher proportion of radium emanation than the waters, and this proportion varies with the spring and with the date of collection.—A. **Boutaric**: The nocturnal radiation at Mont Blanc.—G. **Arnaud**: The affinities of the Erysiphæ and the Paradiopsidæ.—L. **Blaringhem**: Heredity and physiological characters in the hybrids of barley.—G. **André**: The transformations undergone by oranges on keeping. The ripening of oranges by keeping is due to a reduction of acidity, the loss of sugars being relatively small. These changes cannot be wholly due to oxidation, since they are produced in a vacuum. Diastatic action is suggested as possible.—P. **Dangeard**: The evolution of the aleurone grains in castor-oil seed during germination.—M. **Bridel** and Mlle. Marie **Braecke**: The presence of saccharose and aucubine in the seeds of *Melampyrum arvense*. Full details are given of the method of extracting saccharose and the glucoside aucubine from the seeds. Rhinanthine, extracted by Ludwig from the seeds of *Rhinanthus Crista-Galli*, was also stated by Ludwig and Müller to be present in the seeds of *Melampyrum arvense*. The identity of rhinanthine with aucubine has not yet been proved.—H. **Hérissey**: The biochemical synthesis of α-methyl-*d*-mannoside. By the action of the ferment present in germinated lucerne seeds upon *d*-mannose in dilute methyl alcohol solution, α-methyl-*d*-mannoside is formed. Details of method of isolation and proofs of identity are given. —A. **Demolon**: The sulphur-oxidising power of soils. —L. **Mercier**: The larva of *Limnophora aestuum*, a marine Diptera.—A. **Michel**: The interpretation of the profound histological differentiation of the dorsal elytra and cirrus of the Aphroditian Annelids.—J. L. **Lichtenstein**: The determination of egg deposition in *Habrocytus cionicida*.—L. **Roule**: The periodic changes of habitat of the common tunny fish (*Orcynus thynnus*) and their connection with the changes of medium. The migrations of the tunny fish are determined by the temperature and salinity.—L. **Léger** and E. **Hesse**: Microsporidia with spherical spores.—L. **Ravaz** and G. **Vergé**: The germination of the spores of vine mildew. Lime solutions are carbonated too rapidly on exposure to air to exert any toxic action on the mildew spores. Copper-lime mixtures resist the action of rain and dew and preserve their toxic power.—R. **Legroux** and J. **Jimenez**: The factor of growth in cultures of *Leishmania Donovani*.—G. **Bourguignon** and A. **Radovici**: Chronaxy of the sensitive rachidian nerves of the upper limb in man.—E. **Nicolas** and P. **Rinjard**: The vaccination of cattle against bovine plague.

WASHINGTON, D.C.

National Academy of Sciences, Proceedings, vol. 6, No. 11 (November, 1920).—A. **Weinstein**: Homologous genes and linear linkage in *Drosophila virilis*. A long and detailed study with numerous bibliographic references, not lending itself to recapitulation.—F. C. **Hoyt**: The intensities of X-rays of the L-series, III. Critical potentials of the platinum and tungsten lines. A continuation of an earlier work to the classification of some lines that were doubtful.—E. B. **Stouffer**: Semi-variants of a general system of linear homogeneous differential equations.—A. G. **Webster**: Some new methods in interior ballistics. A *résumé* of extended experiments on the principal problem of interior ballistics, namely, to determine the position and velocity of the shot, and the mean temperature and pressure of the gases in the gun. Graphical and analytical methods are used.—C. B. **Bridges**: The mutant crossveinless in *Drosophila melanogaster*. —J. A. **Detlefsen**: Is crossing over a function of distance? The author differs from the conclusion of many students of genetics, and believes that linkage is not a function of distance, that the distance between the two genes may remain fairly constant, and that the crossing over depends upon hereditary factors.—E. E. **Babcock** and J. L. **Collins**: Interspecific hybrids in Crepis. The behaviour of the seven-chromosome Crepis hybrid leads to the belief that there is not such a direct relationship between the two parent species as has been suggested.—C. G. **Abbot**: New observations on the variability of the sun. A discussion of an extended set of observations from July, 1919, to March, 1920, revealing a wide fluctuation in the sun's radiation.—L. P. **Eisenhart**: The permanent gravitational field in the Einstein theory.—G. A. **Linhart**: A simplified method for the statistical interpretation of experimental data.—C. B. **Lipman** and G. A. **Linhart**: A critical study of fertiliser experiments. From a statistical study of fertiliser experiments the authors conclude that no fertiliser experiment as ordinarily conducted is possessed of sufficient practical value to justify the large amount of money, time, and energy involved.

No. 12 (December, 1920).—H. **Shapley**: Preliminary report on pterergates in *Pogomyrmex Californicus*.—J. F. **McClendon**: Hydrogen-ion concentration of the contents of the small intestine. Criticism of the general erroneous impression that the intestinal contents are alkaline.—F. P. **Underhill** and M. **Ringer**: Blood concentration changes in influenza. Both

physiologically and pathologically there is a marked resemblance between influenza and war-gas poisoning, with a marked increase in the concentration of the blood.—E. L. **Nichols** and D. T. **Wilbur**: Luminescence at high temperatures. Announcing the discovery of luminescence at temperatures which are, roughly speaking, above the beginnings of a visible red heat. —S. R. **Detwiler**: Functional regulations in animals with composite spinal cords. The evidence indicates that the factor which is involved in the over-production of motor cells is the stimulus afforded by the connection with the central neurones.—A. S. **King**: Experiments with the tube resistance furnace on the effect of potential difference. The conclusion is that the potential difference acting on the tube is not effective in modifying the spectrum in certain temperature ranges.—J. H. **McDonald**: An application of the porism of four tangents of a twisted cubic.—H. A. **Cheplin** and L. F. **Rettger**: Studies on the transformation of the intestinal flora, with special reference to the implantation of *Bacillus acidophilus*, II. Feeding experiments on man. Attempts to implant *Bacillus bulgaricus* failed, as in the feeding experiments on rats. It appears that *Bacillus acidophilus* milk possesses several advantages over ordinary sour and *Bacillus bulgaricus* milk.—Kilauea Volcano Observatory: A report by the committee of the National Academy of Sciences at the request of the Secretary of Agriculture with reference to desirability of the control of the observatory being assumed by the Weather Bureau.

Diary of Societies.

THURSDAY, JANUARY 5.

GEOGRAPHICAL ASSOCIATION (at Birkbeck College), at 11.45 a.m.—R. L. Thompson and others: Discussion: Geography and History in Schools.

ASSOCIATION OF ASSISTANT MASTERS IN SECONDARY SCHOOLS (at London Day Training College), at 2.30.—Prof. T. P. Nunn: The Purposes of Education.

GEOGRAPHICAL ASSOCIATION (at Birkbeck College), at 2.30.—Sir Halford J. Mackinder: Problems of the Pacific.

ROYAL INSTITUTION, at 3.—Prof. J. A. Fleming: Electric Waves and Wireless Telephony: Electric Oscillations.

GEOGRAPHICAL ASSOCIATION (at Birkbeck College), at 4.—E. N. Fallaize: The Anthropological Institute and the Services it can render to Geographical Students.

CENTRAL ASSOCIATION FOR THE CARE OF THE MENTALLY DEFECTIVE (at University College), at 5.—Dr. G. A. Auden: The Possibility of Co-operation between the School Medical Officer and the Teacher in the Training of Subnormal and Mentally Defective Children.
LONDON HEAD TEACHERS' ASSOCIATION (at University College), at 5.30.—D. J. Collar and T. G. Tibbey: Intelligence Tests in Schools.
ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.30.—Wing-Cmdr. W. D. Beatty: Specialised Aircraft
GEOGRAPHICAL ASSOCIATION (at Birkbeck College), at 5.45.—Lord Robert Cecil: Presidential Address.
INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—Dr. S. P. Smith: Single and Three-phase Commutator Motors with Shunt and Series Characteristics.
PHYSICAL SOCIETY AND OPTICAL SOCIETY (at Imperial College of Science and Technology), at 8.—A. A. Campbell Swinton: The Johnsen-Rahbek Electrostatic Telephone and its Predecessors.
ROYAL SOCIETY OF MEDICINE (Obstetrics and Gynæcology Section), at 8.—B. Whitehouse: Salpingotomy *versus* Salpingectomy in the Treatment of Tubal Gestation.—J. B. Hunter: Short History and Post-mortem Notes of an Interesting Case of Diffuse Carcinoma following Cancer of Cervix.—A. W. Bourne: Hyperthyroidism in Functional Menorrhagia.

FRIDAY, JANUARY 6.

GEOGRAPHICAL ASSOCIATION (at King's College), at 10.20 a.m.—Dr. Fleure: The Co-operation of Historians and Geographers.
GEOGRAPHICAL ASSOCIATION (at Birkbeck College), at 3.—Miss L. Winchester: Some Climate Problems of Modern Palestine.—At 4.—Dr. Hogarth: The Hedjaz.
ROYAL GEOGRAPHICAL SOCIETY (Christmas Lectures to Young People) (at Æolian Hall), at 3.30.—Sir Francis Younghusband: Pictures from Mount Everest.
INSTITUTION OF MECHANICAL ENGINEERS (Joint Meeting with the Society of Chemical Industry), at 6.—G. M. Gill: The Co-operation of the Engineer and Chemist in the Control of Plants and Processes.
JUNIOR INSTITUTION OF ENGINEERS, at 8.—A. E. Bingham: Stone and Marble-working Machinery.

SATURDAY, JANUARY 7.

COLLEGE OF PRECEPTORS, at 11.30 a.m.—Prof. J. Adams: Psychoanalysis and its Value and Limitations from the Standpoint of the Practical Teacher.
ROYAL INSTITUTION, at 3.—Prof. J. A. Fleming: Electric Waves and Wireless Telephony: Electric Waves.
GILBERT WHITE FELLOWSHIP (at 6 Queen Square, W.C.1), at 3.—E. Kay Robinson: British Wild Life.

MONDAY, JANUARY 9.

ARISTOTELIAN SOCIETY (at 21 Gower Street, W.C.1), at 8.—Dr. F. C. S. Schiller, C. Joad, and Prof. R. F. A. Hoernlé: Discussion: Mr. Russell's "Analysis of Mind."
ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.
SURVEYORS' INSTITUTION, at 8.—W. R. Davidge: Problems of Greater London.
ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—Sir Philip Brocklehurst: Across Wadai.

TUESDAY, JANUARY 10.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. J. A. Fleming: Electric Waves and Wireless Telephony: Wireless Telephony.
MINERALOGICAL SOCIETY (at Geological Society), at 5.30.—C. E. Tilley: Density, Refractivity, and Composition Relations of Some Natural Glasses.—A. Russell: Laurionite and Paralaurionite from Cornwall.—W. A. Richardson: A Simplification of the Rosewal Method of Micro-analysis.
INSTITUTION OF CIVIL ENGINEERS, at 6.—A. W. Rendell: Control of Trains in Relation to Increased Weight and Speed combined with Reduced Headway.—Sir Henry Fowler and H. N. Gresley: Trials in Connection with the Application of the Vacuum-brake for Long Freight Trains.
ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (Technical Meeting), at 7.—Dr. B. T. J. Glover and others: Discussion: Should the Manufacturers Supply Figures indicating the Contrast Grading of Gas-light and Bromide Papers?—A. F. Kitching: Demonstration of Some Effects with Ultra-violet Light.—The General Electric Co., Ltd.: Developments Rendered Possible in Projection Work by the Introduction of the Osram Gas-filled Projector Type Lamp.
QUEKETT MICROSCOPICAL CLUB, at 7.30.—Dr. C. Turney: Mosquito Investigation.
RÖNTGEN SOCIETY (at Institution of Electrical Engineers), at 8.15.—Prof. A. O. Rankine: The Structure and Dimensions of Molecules.
ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—J. Whatmough: Rehtia, the Venetic Goddess of Healing.
ROYAL SOCIETY OF MEDICINE (Psychiatry Section), at 8.30.—Dr. R. G. Rows: The Application of Modern Methods in the Treatment of Psychoses.

WEDNESDAY, JANUARY 11.

ROYAL SOCIETY OF ARTS (Mann Juvenile Lecture), at 3.—Dr. W. R. Ormandy: Clay: What it is, where it comes from, and what can be done with it.
INSTITUTION OF CIVIL ENGINEERS (Students' Meeting), at 6.—E. W. Monkhouse: The Economic Aspects of Various Methods of Power-transmission.
INSTITUTION OF AUTOMOBILE ENGINEERS (at Institution of Mechanical Engineers), at 8.—Dr. F. W. Lanchester and R. H. Pearsall: An Investigation of Certain Aspects of the Two-stroke Engine for Automobile Vehicles.

THURSDAY, JANUARY 12.

ROYAL AERONAUTICAL SOCIETY (Juvenile Lecture) (at Royal Society of Arts), at 3.—Major D. C. H. Hume: Boats that Fly.
LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5.
INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—Exhibition of Cinematograph Films.—P. Torchio, with explanatory notes by Dr. C. C. Garrard: Investigations and Tests on High-tension Switchgear.—F. Gill: Telephone Inventors of To-day.—F. Gill: The Audion.—F. Gill: Electricity in the Home.
OIL AND COLOUR CHEMISTS' ASSOCIATION (at Food Reform Club, 2 Furnival Street, E.C.), at 7.30.—A. H. Keable: Super Centrifugal Force and its Application to the Clarification of Varnish and Dehydration of Oil.
OPTICAL SOCIETY (at Imperial College of Science and Technology), at 7.30.—Dr. C. J. Peddle: The Manufacture of Optical Glass.—Dr. J. W. French: The Barr and Stroud 100 ft. Self-contained Base Rangefinder.—T. Smith: The Optical Three Apertures Problem.
INSTITUTE OF METALS (London Section) (at Sir John Cass Technical Institute), at 8—Col. N. Belaiew: The Inner Structure of the Crystalline Grain.
HARVEIAN SOCIETY (Annual General Meeting) (at 11 Chandos Street, W.1), at 8.15.—Dr. G. de Bec Turtle: Some Points on Spasm in the Alimentary Tract (Presidential Address).

FRIDAY, JANUARY 13.

ROYAL ASTRONOMICAL SOCIETY, at 5.—J. S. Paraskévopoulos: Jupiter in 1915 and 1916: Rotation Period in Different Latitudes, from Observations at the National Observatory, Athens.—Prof. G. Forbes: Solar Motion from 1922 Radial Velocities.—Major W. J. S. Lockyer: The Use of a Graduated Wedge in Stellar Classification and Parallax Work.

Classics and Science.

LORD MILNER, in his presidential address to the Classical Association on January 6, made a notable declaration of the unity of educational purpose of classical and scientific studies. He pointed out that to the mind which had received real enlightenment there could be no antagonism between these two great branches of human knowledge. "All modern science had its roots in the classics, and, on the other hand, no man imbued with the spirit of the great classical writers could be lacking in respect for science or fail to recognise its supreme importance to the progress of mankind." Lord Milner went on to say:—

"I wonder what Plato and Aristotle, could they reappear among men to-day, would say to an education that was purely linguistic, even if the literature with which it occupied itself was the best ever known. Looking with wondering eyes on the achievements of science which had transformed the world since their day and given to man command over physical forces such as they had never dreamed of, would they not be seized with an intense desire to probe these marvels to the bottom, to know all about their causes, the methods and the steps by which such great results had been attained? And what would they think of a man who, living in the midst of these achievements, took no interest in them except in so far as they affected his personal convenience and well-being, enabling him to satisfy his wants cheaply, to travel with rapidity and comfort, to communicate in a few minutes with the uttermost ends of the globe, to escape suffering, avert disease, and even postpone the advent of death, and who never felt impelled to go more deeply into the matter and to learn something of the inner nature of the mysterious forces the discovery of which was so rapidly transforming the life of men upon this earth? Any Greek philosopher revisiting the world to-day would condemn such a man as a misfit—a creature unsuited to its environment."

With this conception of the close relationship between classical learning and scientific discovery most scientific workers will be in cordial agreement. The common enemies of both are ignorance, sordid commercialism, and general public indifference to intellectual light, whether it comes from the past or the present. There was a time when this was not so clearly recognised as it is to-day, and when classical scholars placed followers of experimental science among the barbarians. Tradition, method, social distinctions and professional prospects were then all on the side of the classics of Greece and Rome, and the most capable pupils were directed to the study of them and discouraged from devoting attention to modern scientific studies. It was claimed that instruction in classical languages was particularly valuable in developing accuracy, training reasoning powers, improving the memory, and cultivating all the faculties necessary to make the best use of life in any field. Psychologists have, however, destroyed the educational concept upon which this claim is based, and it is no longer believed that the exercise of the mind on one kind of material improves the faculty to deal with other kinds. No subject can therefore be put forward as affording unique general training in mental faculties or powers.

We are glad that Lord Milner did not base his plea for classical studies upon the grounds of the mental discipline secured through concentration upon the letter, but dealt rather with the spirit manifested in the literature and culture of ancient Greece and Rome and its guidance for life to-day. Whatever may have been the true source of Greek thought and discussion, whether intuitive or acquired, our own intellectual culture is unquestionably of Greek origin. While Latin was first taught as a medium of expression, and for use in the needs of life, Greek was studied for the knowledge to be gained through it. We do not hesitate to pay tribute to the brilliant genius of Ionian philosophy, the careful work of Hippocrates and his school, and the richness of the Alexandrian epoch. In the teaching of the Ionian school it is possible to find, as Prof. Gomperz has pointed out, two of the corner-stones of modern chemistry—the existence of elements and the conception of a single fundamental or primordial matter as the source of material diversity. Advanced views relating to the shapes and motions of bodies in the solar system were held at a very early date in Greek

history (though they were afterwards superseded by childish ideas), and the first phase of the history of thought upon organic evolution began with early Greek philosophers in the seventh century before the opening of our era, while its effects on Christian theology and Arabic philosophy were felt for more than two thousand years. Acquaintance with these and other achievements of Greek genius should be part of the intellectual equipment of every educated man, and the science student can find even more to admire in that wonderful age than can the purely literary scholar.

While, however, we hold the philosophers of Greek antiquity in highest honour, it must be confessed that the whole of Greek natural knowledge has little bearing upon the principles, methods, and practice of modern science. Scarcely a scientific work of to-day contains a reference to contributions to the subject by Greek philosophers, and their guesses or observations may be said to be disregarded by scientific discoverers generally. While the mathematician esteems the achievement of Euclid and the investigations of Archimedes, and the physician finds much to admire in the works attributed to Hippocrates, the chemist and experimental biologist are disposed to regard Greek speculation on their respective subjects as fruitless. Indeed, from the point of view of practical chemistry, it would be more reasonable to study Arabic literature than Greek. The creative genius of the early Greeks is undoubted, but its results are negligible in comparison with the work of modern science.

The value of acquaintance with Greek learning is not in the material knowledge itself, but in the spirit which created it. The Greeks possessed to a high degree the spirit of scientific curiosity and the desire to find a natural explanation for the origin and existence of things which is the ground motive of progress in science. The aim of Greek thought was the unification of disconnected knowledge. This laid the foundation of synthetic science, but carried with it the tendency to reduce natural phenomena to a rigid geometrical or logical system. It is possible that the modern science student would be all the better if given a trend in the same direction, as experimental inquiry alone is apt to be narrow and must be specialised. Even neglecting this philosophical aspect of science, the early Greeks manifested supremely the characteristics of true apostles of science. Passionate regard for truth, disinterested research, imagination, acute reasoning, and creative intelligence were the essence of the Greek spirit, and they are elements of the unalterable germ-plasm which transmits the scientific temper throughout the ages. Because inspiration and constructive thought are necessary to the student of natural knowledge, the writings of Greek philosophers cannot be neglected by him without detriment to his intellectual equipment.

It is the human side of Greek thought and action that the science student should know, and the scientific facts themselves are ancillary to it as a means of training. Science as studied in most schools is a spiritless performance and has not that contact with human nature required to make it appeal to most pupils. Attention to the history of great scientific discoveries may perhaps tend to counteract the conception of science as a mere repository of facts and a vocational study. Greek philosophy can usefully take an important place in such a course, but consideration must be given to the most appropriate stage at which to introduce it. It is now generally agreed that there should be no specialisation of studies below the age of about sixteen years, so that up to this stage all students should have formed the same foundations of a general education, including both the literary and the scientific elements. If the preliminary training thus received in classics enabled an average pupil to read original Greek texts by sixteen years of age, the value of this attainment to the student who then proposes to devote himself mainly to science cannot be doubted. As, however, such proficiency is rare, it would appear that the case for the teaching of Greek or Latin holds chiefly for those who propose to continue the study to an advanced stage, and that for students who propose to specialise in other directions preliminary instruction which is necessarily truncated serves no very useful purpose.

A subject of study should be considered as an instrument of service—mentally, morally, and materially—as a working part of the machinery of life. If the preliminary training in classics cannot reach this stage of attainment for science students, then obviously it would be better to absorb the spirit of Greece through translations than to spend time at what must prove a vain study so far as reading original texts with intelligence is concerned. No student who proposes to devote himself to science could hope to render Aristotle into English in the style of the translation now being published by the Clarendon Press under the editorship of Mr. W. D. Ross, or of Sir Arthur Hort's translation of the "Enquiry into Plants" from the Greek of Theophrastus published in the Loeb Classical Library, to mention two instances only. Whatever may be urged as to the value of the study of the classics to science students must refer chiefly to the substance of the best works in these languages, and that can be gained from translations.

Acquaintance with the Greek spirit through such means is much needed in science teaching when the age is reached at which a student can appreciate the systematising aspects of science. Early interest in science comes through wonder and delight in the intrinsic beauty and charm of natural phenomena, and is followed by interest in the use of the forces of Nature by man. With adolescence comes the power of appreciating systems of theoretical completeness and unity, and it is then that attention may usefully be turned to the thoughts of Greek philosophers. Young pupils are very rarely impressed by unifying principles and philosophical speculations whether placed before them in Greek or their own language. Their work in science is thus almost necessarily limited to acquaintance with perceptual phenomena, and conceptual ideas make little appeal to them. Similarly in historical studies striking episodes and dramatic events are more easily intelligible to immature minds than the constitutional or other causes which produce them. Probably a grammatical generalisation is more readily understood than a principle derived from laboratory measurements, and on that account pupils who have been trained to apply scientific method to language may be better prepared to take up the study of science seriously than one in whose mind there is nothing but loose ends. Whether Greek and Latin are essentially the most suitable languages for promoting this sense of law and order, as well as facility in the art of expression, is a matter of opinion. There may on these grounds be a value in preliminary training in classics to students who propose to devote themselves mainly to scientific pursuits, but there is so much in Greek science and philosophy that cannot be understood without acquaintance with natural knowledge that an even stronger plea can be made for training in science for those who intend to give their chief attention to classical studies.

The Hormone Theory of Heredity.

Hormones and Heredity: A Discussion of the Evolution of Adaptations and the Evolution of Species. By Dr. J. T. Cunningham. Pp. xx + 246 + 3 plates. (London: Constable and Co., Ltd., 1921.) 24*s*.

IT would be no exaggeration to say that holes could be picked in any theory of heredity as yet put forward. The problem is one of great difficulty and complexity, and when we think of the enormous number of qualities or "factors" conveyed in the minute space of an ovum, or still more in a single sperm-cell, it seems at first sight impossible to believe that all these qualities are "represented," rather than that the presence of certain of them, which might be called "key-factors," imply the development of numerous others. But, however this may be, the thought suggests itself that perhaps the knowledge we possess of the nature of protoplasmic structure and function is not yet sufficiently advanced to warrant the statement of any theory professing to be adequate. We are, indeed, in some doubt even with respect to certain fundamental facts. As will have been clear to readers of the correspondence in these columns, in which Sir Archdall Reid and others have taken part, the actual meaning of many of the terms used is in dispute.

It may be of use to attempt to express in a few words the main question at issue without using language of uncertain connotation. Suppose, then, that an organism is exposed to a new set of external conditions. Some forces or influences acting upon it are changed, and the effects produced in the organism, which we call its "reactions," are not the same as before. These reactions are, of course, conditioned by the nature of the organism itself, and may or may not be of such a kind as to be of benefit to it in adjustment to the new state of affairs. If they are so, they are sometimes called "adaptations." But this term is apt to suggest to certain minds a species of directing agency, and is best avoided. In any case, the length of life of such an organism will be dependent on its response to the changed conditions. Those organisms with the longer life naturally leave more offspring, which will be more like their parents than like the offspring of parents which have responded less favourably to the change in environment. The first-mentioned offspring will, therefore, respond to this changed environment in the same way as did their parents, and probably some of them, owing to the random shuffling of the material of the germ-cells, more favourably.

It will be seen that we are not justified in speaking of such a case as one of "inheritance of acquired characters." If the response in question were continued in the offspring after the altered environment had returned to its original or some other state, an alteration in the "germ-plasm" might be supposed to have been produced. But some difficulty arises here in respect of cases in which it appears that a change may be persistent for a few generations and that then reversion to the original mode may occur. Are such cases to be regarded as changes brought about in the germ-plasm? We note how difficult investigation is made by the length of time needed for the tests. Many researches are in progress at the present time, and

we may look for much light from them. The conviction seems to be growing that at all events a slow and gradual change in the germ-plasm may be produced by altered conditions, although the main lines of heredity may be determined by ancestral nature.

Many obscure facts have to be taken into account, and it is no wonder that the author of the book before us finds it an easy task to show how unsatisfactory are the various theories of heredity and variation that have been suggested. He therefore puts forward a new one, which appears to have taken its present form on account of the renewed attention attracted to the effect of the chemical products of one organ on the activity of another—on account of the discovery of the mechanism of pancreatic secretion by Starling and the present reviewer in 1902. The hypothesis that every tissue of the body gives off its own specific chemical product, and that this product has its effect to a greater or less degree on all other tissues, was put forward by Brown-Séquard and d'Arsonval as early as 1869, but was thrown somewhat into discredit by the uncritical use of it by the former. Dr. Cunningham gives the credit of the first suggestion to Claude Bernard in 1855, but we regret to have been unable to find the statement referred to. It would be of much interest to have the exact reference.

The hormone theory of heredity may best be given in the words of its propounder: "We have within the gonads numerous gametocytes whose chromosomes contain factors corresponding to the different parts of the soma, and these factors or determinants may be stimulated by waste products circulating in the blood and derived from the parts of the soma corresponding to them" (that is, to the determinants). Thus the effect of chemical products on any particular organ or tissue in the soma is to be supposed to be exercised in the same way on the "determinant" in the germ-cell which afterwards gives rise to such organ in the progeny. For example, the exostosis on the frontal bone of stags, formed as a result of repeated butting, would give off products, not necessarily different in kind from those of bone in general, but in increased amount, and thus stimulate the corresponding factors in the germ-cells.

While it would perhaps be rash to deny the possibility of a process of this kind, the objection might naturally be made that when applied to the inheritance of bodily structures in general, or of changes in them, it argues so enormous a variety of "hormones" as to seem almost incredible. Not only so, but the chemical product of each organ and tissue must act on the germ-plasm in a way which leads to the formation of a tissue like that by which the hormone was formed. In view of the difference between the structure and activity of the germ-plasm and those of the various constituents of the soma, are we justified in supposing that a particular chemical compound will affect both in the same way or even in a similar way? Moreover, waste products would be expected rather to have a retarding than a stimulating influence on similar reactions. But it might be held that the hormones in question are not waste products in the ordinary sense, and that the precise name is immaterial.

The possibility cannot be denied that, however inaccessible to nervous action the germ-plasm may be, it must be affected by chemical agents in the blood. Indeed, Stockard's experiments, to mention a single instance only, show that this is so with alcohol. But in such cases the effect is of a more or less generalised nature on the progeny, and the existence of tissue products of the kind demanded by Dr. Cunningham's theory is not yet demonstrated. As Prof. Swale Vincent has pointed out, it is remarkable how few "internal secretions" have actually been shown to exist as chemical individuals. Although it may savour too much of mysticism, it is open to question whether the original form of Dr. Cunningham's theory, in which "influences" were spoken of, might not be the more cautious and wiser one as yet. The loss of differentiation in the growth of tissues *in vitro*, except in the proximity of another tissue, no doubt indicates some kind of influence by one tissue on another. But the fact that this influence disappears when the new cells wander away into the culture fluid is difficult to reconcile with a chemical product.

Notwithstanding this objection, the theory must be given the credit of introducing functional or physiological considerations into the problem, as does the somewhat similar one of Delage. Most theories seem to be content with the purely structural view of rows of determinants in chromosomes and the shifting about of these. The difficulty in those theories which limit the transmission of hereditary characters to the chromosomes is that these exist as distinct entities only at the time of karyokinesis, while even the nucleus itself is but a part of the cell in functional relation with the whole. Whether the chromosome view is necessarily involved in Mendelian interpretations is subject to doubt, however significant the experimental facts may seem. Bateson appears to be unconvinced, and states that the results of such experiments have not solved the problem of adaptation, while Brachet has obtained evidence that the ovum, when fertilised after removal of the nucleus, can transmit characters of the female parent.

Dr. Cunningham appears to be justified in his complaint that, although his theory was published in 1908, later writers have put forward similar

views without reference to his work. In the book before us he includes a detailed account of his experiments on the origin of somatic sex-characters, and uses these as the main support of his theory. One must admit that explanation on other lines is extraordinarily difficult. The discussion of the origin of the scrotum on pp. 147 and 148 is of much interest, although, no doubt, objection may be taken to the view of its origin as a kind of traumatic hernia.

Space forbids detailed reference to the many other facts of importance brought forward, such as the difference between specific and adaptive characters, the origin of new dominants, the presence of useless characters, continuous and discontinuous variations, and so on. Loeb's "tropism" theories are adversely criticised. The facts and views put forward cannot be neglected by investigators of the problems of heredity, and the book as a whole requires careful consideration. It is of particular value in bringing to notice a theory which was previously known to an inadequate degree, and, although modifications will doubtless need to be made, the various facts and theories contained in the book must not be forgotten in the formation of a complete theory of heredity. Dr. Cunningham's theory has the undoubted merit of suggesting new forms of experiment, and everyone will agree with the opinion expressed on p. 64: "Further light on the sex problem, as in many other problems in biology, can only be obtained by more knowledge of the physical and chemical processes which take place in the chromosomes and in the relation of these structures to the rest of the cell."

W. M. BAYLISS.

Medicinal Chemicals.

Organic Medicinal Chemicals (Synthetic and Natural). By M. Barrowcliff and F. H. Carr. (Industrial Chemistry.) Pp. xiii + 331. (London: Baillière, Tindall, and Cox, 1921.) 15*s.* net.

IN writing this book Messrs. Barrowcliff and Carr had in mind the production of a critical compendium of methods for the manufacture of organic medicinal chemicals, which would be useful to teachers and to those occupied in research work in the industry itself. The idea was to restrict attention to those published processes which seem capable of industrial application and are therefore of first importance when improvements are under consideration.

It may be said at once that for the ends in view the volume leaves little to be desired. The information given is well selected and reasonably complete, though it clearly does not exhaust the authors' knowledge of the subject: the descriptions are clear and easy to follow.

Considerations of space are no doubt responsible for the brevity exhibited in some cases; thus, under pilocarpine there is no reference to the alkaloids which accompany it in jaborandi, though any attempt to make pilocarpine is sure, sooner or later, to bring the operator into contact with *iso*-pilocarpine. The authors have every excuse for not embarking on a critical *résumé* of the tangled chemistry of digitalis by way of introduction to their description of the manufacture of the various products which appear in commerce as active principles of this drug; nevertheless, there can be no question that such a *résumé* would have been useful. It should be added, however, that the authors have only themselves to thank if their readers prove exacting in such matters, because in most cases they have provided excellent summaries of the kind indicated, which serve to emphasise the few cases in which they are lacking.

The subjects dealt with are grouped for the most part according to therapeutical applications—*e.g.* anæsthetics, narcotics, analgesics—though this arrangement is departed from when it is more convenient to group together a series of related substances such as the naturally occurring alkaloids and organo-metallic compounds. As already indicated, little that is essential has been omitted, but it might have been a good plan to refer quite briefly at the end of each section to any particularly promising drugs suggested by recent investigations. Thus, under local anæsthetics, mention might have been made of benzyl alcohol and certain of its homologues and derivatives, since these are already coming into use, at any rate in the United States, as a result of the work of Macht and his collaborators.

A drug which is not referred to, but is of special interest at the present time, is santonin, for the plant from which it is made grows in Soviet Russia, and there also is the only factory producing the drug. The plant is, however, now being grown experimentally in the United States, and a possible new source of supply has been found in India. Santonin is one of the best-known anthelmintics, a group of drugs which merits more attention than has been given to it by British chemists. The British Empire probably possesses among its coloured populations in the tropics more victims of hookworm, to mention only one of this group of parasites, than any other country, with the possible exception of China, and, like China, it is largely dependent on public-spirited citizens

in the United States for the distribution of suitable anthelmintics and the conduct of anti-hookworm campaigns within its borders. Processes for the preparation of these drugs are well-known, and the authors would be rendering a further service to their colleagues if they would add a section on anthelmintics when a new edition of their book is called for.

The volume is well produced, and contains a number of useful diagrams of plant and a good index. The proof-reading has been carefully done, and printers' errors are commendably few.

T. A. H.

Some New Text-books on Radio-telegraphy.

(1) *Wireless Telegraphy and Telephony: An Outline for Electrical Engineers and Others.* By L. B. Turner. Pp. xii + 195 + 24 plates. (Cambridge: At the University Press, 1921.) 20*s*. net.

(2) *Thermionic Tubes in Radio-Telegraphy and Telephony.* By John Scott-Taggart. Pp. xxiii + 424. (London: The Wireless Press, Ltd., n.d.) 25*s*.

(3) *Continuous Wave Wireless Telegraphy.* By Prof. W. H. Eccles. Part 1. Pp. vii + 407. (London: The Wireless Press, Ltd., n.d.) 25*s*. net.

(4) *Principles of Radio-Communication.* By Prof. J. H. Morecroft, assisted by A. Pinto and W. A. Curry. Pp. x + 935. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1921.) 45*s*. net.

(1) IT is a pleasure to come across a technical book, like that by Mr. Turner, which has the literary qualities of clearness, life, and continuity. In too many scientific text-books the manner is as cold as the matter is dead and already dissected; the parts are evident, but the whole is left to the constructive imagination of the reader. A book may be crammed with exact information, and yet be so unreadable as to have little value from the point of view of education. Even quite a slight historical framework adds human interest and may guide the student along the course of thought which resulted in discovery, and a text-book in which such a framework exists is therefore much more educative than one which merely states the physical facts, however accurately.

Unfortunately for the average student a sound knowledge of the mathematics of motion is required in the study of the production of high-frequency currents on account of the large number of variables involved, especially when the converter is a thermionic valve or an arc. Again, unfortunately, this branch of mathematics is known, in spite of Newton, by the entirely unilluminating and indeed repellent name of "the differential calculus." "Calculation by differences" does not suggest motion any more than "bits of iron" would suggest a locomotive, and it is doubtful if the would-be engineer realises that in avoiding this unpleasantly named subject as much as possible he is debarring himself from the most interesting and useful branch of mathematics. Could not mathematical teachers make the learning of the laws of motion more interesting than the study of geometry in the same ratio as a kinema is more attractive than a photograph?

In the books under review mathematics are freely used except in (2) Mr. Scott-Taggart's "Thermionic Tubes," which is quite an encyclopædia of types and circuits, but does not enter deeply into exact theory, although the graphical explanations are very useful. Mr. Turner has the happy knack of working his equations so naturally into the text that the deductions which he makes from them are almost self-evident, and although his book contains only 190 pages, there is but little that could be added with advantage to the outline which he has set himself to give. An interesting personal opinion is given on p. 11, where he says he can derive no satisfaction from the usual semi-Hertzian diagram of wave radiation over a conducting surface; but why should Dr. Howe's model, in which an inverted conducting cone with its apex at the transmitter is substituted for the upper atmosphere, be any simpler? It merely evades the question of where the lines go in space, and neglects the fact that aircraft experiments indicate that their directions are probably such as are shown in the Hertzian diagram. The expression of the opinion, however, shows the perfect honesty with which Mr. Turner treats his readers.

The other books are different in scope and style. (3) Dr. Eccles's is a first volume only and is devoted to the theory of electromagnetic induction and conduction on metallic circuits and vacuum tubes; both branches of the subject are treated clearly and in great detail, and a sound basis is laid for a thorough understanding of the technical applications which will presumably form the greater part of his second volume.

(4) Few, if any, books on radio-telegraphy have covered so many details of the subject as Prof. Morecroft's "Principles of Radio-Communication," and there is little connected with the functions of radio-gear which he does not touch upon.

A good deal of original matter is incorporated in the book, and, as the author says in his preface, much on which further experiment may be based. The descriptions of instruments and the theories of their actions are clear, but though the text is, on the whole, quite simply written, the mass of material is somewhat overwhelming, and one cannot help feeling that this is due, at least in part, to the space given to certain sections being out of proportion to their importance. It is a pity that the appearance of the book is marred by the very careless printing of the many half-tone blocks with which it is illustrated.

It is rather remarkable that actual radio-telegraphic transmission from station to station is dismissed in these text-books in a very few pages; in fact, their subject is rather radio-telegraphic instruments than radio-telegraphy. Atmospherics and their elimination, the laws of the transmission of power, the causes of distortion of wave fronts, and the relative telegraphic efficiencies of various methods, are the most important problems in radio-telegraphy to-day, and their solution is incomparably more urgent than that of any question of purely instrumental theory.

Our Bookshelf.

The New Physics. By Dr. A. C. Crehore. Pp. xii + 111. (San Francisco: *Journal of Electricity*, 1920.) 2 dollars.

OBJECTION may be raised against the title of this book, on the grounds that it has been used before, and that it seems to imply an exaggerated sense of the importance of the views therein expressed. The physical dimensions of electric and magnetic quantities are first discussed, and the author, rightly we think, emphasises the importance of retaining the specific inductive capacity, k, and the permeability, μ, in the equations. He supposes that k may be considered as the reciprocal of a velocity, and Maxwell's relation then automatically determines μ as a quantity of the same kind. This gives a single system of units for all quantities in terms of length, mass, and time, electric and magnetic charges appearing as quantities of the same dimensions. Dr. Crehore's next step is far more questionable—he assumes that the dimensions of mass are those of a velocity. We cannot attach much importance to the first of the "two equally forceful reasons" he advances in support of this assumption. His new expression for Planck's constant may be the result merely of a numerical coincidence. His second reason is based on the gravitational equation which he has developed, but this equation has been criticised, and must be considered as still *sub judice*. As a literary production the book cannot be commended, and the habit of stating results "in advance of the narrative" tempts one to suggest that it should be read backwards.

Fermat's Last Theorem: Proofs by Elementary Algebra. By M. Cashmore. Third edition. Pp. 67. (London: G. Bell and Sons, Ltd., 1921.) 2*s.* 6*d.* net.

THE first attempt to prove Fermat's last theorem contained in this edition repeats a fallacy to which attention has already been directed in NATURE, Oct. 30, 1919. On pp. 18, 21, "quantities" t and u are defined, and it is assumed that these quantities are integers, which is not generally the case. In the second attempt there is a fallacy, pp. 34–35, relating to the divisibility of numbers. The pamphlet ends with a version of Barlow's attempt to prove the last theorem, taken from the 1811 edition of his "Theory of Numbers." Barlow's attempted proof contains a well-known fallacy, which need not be pointed out here.

In view of the considerable erroneous literature concerning Fermat's last theorem it may not be out of place to direct attention to two valuable additions to the correct literature which have appeared since the last edition of Mr. Cashmore's book was reviewed in NATURE. They are: (1) Mr. L. J. Mordell's "Three Lectures on Fermat's Last Theorem," and (2) a chapter in vol. 2 of Prof. L. E. Dickson's "History of the Theory of Numbers."

W. E. H. B.

The Physical Properties of Colloidal Solutions. By Prof. E. F. Burton. Second edition. (Monographs on Physics.) Pp. viii + 221. (London: Longmans, Green and Co., 1921.) 12*s.* 6*d.* net.

THE second edition of this work conforms in general to the plan of the first, *i.e.* it gives an account of the properties of suspensoid sols from the point of view of the physicist. The Brownian movement and the electrical phenomena accordingly claim the largest share, while the optical properties of small particles are also treated with unusual fulness. The rather difficult investigations dealing with these matters are summarised with great skill and lucidity. Apart from some omissions—among which the X-ray analysis of colloidal particles, Pauli's work on the effect of radiation, and Ostwald's on the protection of Congo-rubin sols must be mentioned—all important advances made since 1914 have been embodied in the present edition. This applies specially to the gradual breaking down of all "valency rules" in electrolyte coagulation. The book is excellently produced, and will be welcome to all serious students of the subject.

An Introduction to Organic Chemistry. By D. Ll. Hammick. Pp. viii + 258. (London: G. Bell and Sons, Ltd., 1921.) 6*s.*

MR. HAMMICK's book provides an introduction to organic chemistry suitable for junior students, and not differing in any notable way from numerous other books of similar standard. Experiments are described.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Chemical Warfare.

SIR EDWARD THORPE, in his review of Victor Lefebure's book, "The Riddle of the Rhine," in NATURE of November 10, p. 331, quotes a passage which deals with my own work during the initial stages of the war, and that of the Kaiser Wilhelm-Institut für Physikalische Chemie, of which I am the principal. The intention is to make the world believe that the materials for gas warfare were prepared by the German military authorities and chemical industry for the intended war, and that experiments with this end were carried out in my institution, if not previous to the war, at least from August, 1914, onwards.

It is always dangerous to attempt to form a correct estimate of the intentions of others from the traces of events they have left behind them. But the greatest errors must necessarily arise if an outsider tries to deduce from his own impressions the intentions of men whose ways of thinking he does not know and cannot understand.

Perhaps there might have been some ground for suspicion if Germany could have foreseen the trench warfare, and if we could have imagined that the German troops could ever be held up for weeks and months before the enemy's wire entanglements. But previous to the war, and up to the Battle of the Marne, everyone in Germany imagined that the course of the war would be a succession of rapid marches and great pitched battles, and what use would gas have been to a field army in such a war of movements? I think I may safely say that during the course of the war I became acquainted with every man of any importance in the army, in industry, and in science, who had anything to do with chemistry as applied to military offensive and defensive operations, and that I am well informed regarding the development and the course of chemical warfare. Yet among all these men I have never met one who, previous to the war or during the first two months of its course, had conceived the idea of providing the field army with gas, or had made experiments or preparations for such a purpose. We had actually first to read in the French, Italian, and English Press—as, for instance, in the *Pall Mall Gazette* of September 17, 1914—of the terrible things that were in preparation for us before we began to make similar preparations in view of the commencement of the war of position.

As regards my own institution and its work during the first months of the war, that intelligent person who, according to the passage in Lefebure quoted by Sir Edward Thorpe, observed my activities in my institute from behind a wall, lacked the gift of interpreting correctly what he saw and heard. Visitors in grey Headquarters motors did indeed come to my institution in August, 1914, though not to see me upon the subject of chemical means of warfare, but because Headquarters were very anxious to know how motor spirit could be made proof against the cold of a Russian winter without the addition of toluol. The question of gas as means of warfare did not begin to engage our attention until the first three months of war had passed.

In war men think otherwise than they do in peace, and many a German during the stress of war may have adopted the English maxim, "My country, right or wrong," but that German science and industry before the war made preparations with deliberate intent for gas warfare against other nations is an assertion that, in the interest of the necessary interdependence of the nations in the realms of science and industry, must not be allowed to go uncontradicted in so serious and respected a journal as NATURE.

F. HABER.

Kaiser Wilhelm-Institut, Berlin-Dahlem,
December 17.

HERR GEHEIMRAT HABER takes exception to the quotation I made from Major Lefebure's "Riddle of the Rhine," in the course of my notice of that book, on the ground that it implies that the German military authorities were prepared to ignore their undertaking, under the Hague Convention, to abstain from the use of asphyxiating or deleterious gases in war, if not for some time before, at least at its outbreak in the summer of 1914. I have, of course, no precise knowledge of the intentions of the German military authorities, but it was not unreasonable to surmise that these authorities, who deliberately intended to violate the treaty with Belgium, would not hesitate—as, indeed, the sequel showed—to disregard their promise under the Hague Convention if and when it suited their purpose to do so.

As regards their intentions, Field-Marshal Lord French, in his dispatch after the first German gas attack, with which Prof. Haber was concerned, wrote: "The brain-power and thought which has evidently been at work before this unworthy method of making war reached the pitch of efficiency which has been demonstrated in its practice shows that the Germans must have harboured these designs for a long time."

"It is an arresting thought," says Major Lefebure, "that even as early as 1887 Prof. Baeyer, the renowned organic chemist of Munich, in his lectures to advanced students, included a reference to the military value of these compounds"—*i.e.* to substances intended to produce temporary blindness.

Prof. Haber, it will be observed, does not explicitly deny the accuracy of the statements made by the "neutral," as quoted by Major Lefebure. Indeed, the account is too definite and specific to be set aside by irrelevancies. It is probably true that "everyone in Germany imagined that the course of the war would be a succession of rapid marches and great pitched battles." Some people on this side of the Channel were of a different opinion. But even the vain imaginings of "everyone in Germany" were not necessarily inconsistent with the use of poison gas. It was used on the Eastern front by the Germans when there was little or no question of trench warfare or wire entanglements. Prof. Haber states that he never met a single person who previous to the war or during the first two months of its course had conceived the idea of providing the army with gas. "The question of gas as a means of warfare did not begin to engage our attention until the first three months of war had passed."

The first gas attack was launched in April, 1915, so that on Geheimrat Haber's own showing this method of conducting war was engaging attention at least six months before it was used. After all, the essential point is that it was used, and first used, by the Germans, and in flagrant contravention of a solemn promise given to the world; at what precise

period they decided to be false to their obligation is a matter of secondary moment.

The implication that the Allies were contemplating the use of poison gas as early as September, 1914, is so notoriously at variance with truth that it scarcely needs serious refutation. If Geheimrat Haber could only have been present when Lord Kitchener made his dignified protest in the House of Lords, or have been a personal witness of the wave of indignation and disgust which swept over the country at the Germans' breach of the rules of war, he would not have penned his statement. We were made aware of the rumours that were being spread through the German Press, but no credence was attached to them in this country. The German Empire, even to the last, had its "reptile Press" as in the days of the Iron Chancellor. The author of the Ems telegram was an adept in the art of circulating false rumours and misleading statements, and there were those who sought to better even his example during the fateful and, for the Germans, disastrous years of the war. Even now Germany does not know half the truth.

I agree with Prof. Haber that in war-time men are apt to think otherwise than they do in peace, and this is, doubtless, particularly true of his countrymen. Their ethical standard, apparently, varies with the two conditions—which seems a sufficient reason why they should abstain from war. Those who use poison gas are not "bonnie fechters."

The menace of the continued use of poison gas in warfare is a disgrace to civilised humanity. That menace really rests with Germany. If she would undertake for the future to be true to her obligation under the Hague Convention other nations would willingly follow her example.

They were reluctantly compelled to follow it in consequence of her action at the Battle of Ypres. They would far more promptly follow her lead if she announced her intention to discontinue the practice and gave the world a sufficient assurance of good faith.

Prof. Haber could render no greater service to civilisation and humanity than to use his great influence and pre-eminent position as a man of science in inducing his fellow-countrymen to remove what is a stigma upon their *Kultur*.

T. E. THORPE.

Some Problems in Evolution.

I AM quite as averse from "wasting time in endless and futile controversy" as Prof. Goodrich, but I cannot help thinking that so long as he and Sir Archdall Reid refuse to admit what seem to most biologists obviously true statements their arguments must be answered. Prof. Goodrich states in NATURE of December 22 last that there is no contradiction between his proposition that characters, whether new or ancient, may be inherited provided they are possessed by both parents, and my reply that a character may be inherited when it is apparent only in one parent or in neither. If we omit what is common to both of these propositions it follows that in Prof. Goodrich's opinion there is no difference between "both parents" on one hand and "one or neither parent" on the other.

Prof. Goodrich complains that I do not distinguish between the variation and the resulting character. In his presidential address he maintained that the word "variation" should mean the extent or degree of difference between individuals, not a new character or assemblage of characters, such as a colour or spot on a butterfly's wing, but a difference which can be measured or estimated. "We shall then find," he writes, "that a variation is either due to some change in the complex of germinal factors or to some change in the complex of effective environmental stimuli." Here Prof. Goodrich and I are in complete agreement. Where, then, is any difference of opinion or room for controversy? The difficulty reappears in the next paragraph of Prof. Goodrich's letter, in which he states that he agrees with Sir Archdall Reid that there are two kinds of variation but only one kind of character.

Although I have honestly tried to do so, I fail to see any meaning in this statement. After all, words and terms are seldom completely satisfactory expressions of what we mean; they obtain their meaning by actual or implied reference to facts of observation. I have lately been in the habit of using the term "character" more frequently than the term "variation," because the latter is often ambiguous, but I know of no such difference of meaning between the two terms as is assumed by Prof. Goodrich and Sir Archdall Reid. How can we define characters satisfactorily except by comparison—that is, as differences between one individual, or one type, and another? For example, the rose comb is a character of certain fowls as compared with the single comb. What do we gain by asserting that the difference between the rose comb and the single is a variation, but the peculiarity of the rose comb is a character? The only questions of importance are the origin and the heredity of the rose comb. We understand one another when we say that the rose comb is inherited. It is quite superfluous to insist, as Sir Archdall Reid does, that characters are not transmitted, but only predispositions. No one supposes at the present day that the fowl's egg or spermatozoon has a rose comb, but we know that there may be something, whether we call it determinant, factor, or gene, in egg or sperm which causes the rose comb to develop in the resulting organism. And yet Sir Archdall Reid argues as though it were a remarkable discovery that characters are not present as such in the fertilised ovum from which an organism develops—an idea that has been obsolete since the Middle Ages. Therefore, he asserts, there is only one kind of character, but there are two kinds of variation. The hoof of a new-born foal has developed without any external mechanical stimulus; when I practise rowing for some time I develop epidermic corns on the palms of my hands. According to Sir Archdall Reid, these are characters of the same kind, equally innate, acquired, and inherited. Yet he has himself insisted on the distinction between characters developed under the "stimulus of nutrition" and those developed under the "stimulus of use," the same distinction, with his own peculiar misuse of the word *stimulus*, which is generally recognised by biologists.

Avoiding altogether the use of the terms "variation" and "character," we may congratulate ourselves that there is agreement on the proposition that a difference of form or structure may be due either to a difference of germinal factors or to a difference in effective environmental stimuli. And then we can get on with the investigation of the problem of the relation to evolution of these structural differences.

But, as I have endeavoured to show elsewhere, among those characters which are more or less completely hereditary there are two kinds, in a vast number of cases definitely distinguishable: the adaptive characters on one hand and the non-adaptive on the other. The adaptive characters exhibit a definite relation to habits and external conditions, and, as a rule, they exhibit recapitulation in development. The

non-adaptive characters show no relation to differences of habit or environment, and, as a rule, develop directly without recapitulation. I have instanced the adaptive characters of Pleuronectidæ (flat-fishes) on one hand and their specific and generic characters on the other. The adaptive characters of flat-fishes exhibit one of the most remarkable cases of metamorphosis and recapitulation in the whole field of zoology, while the various peculiarities of the scales, as examples among specific and generic characters, show neither recapitulation nor any relation to habits and conditions of life. Thus, instead of agreeing that there is only one kind of character, I find it necessary to distinguish three kinds, one due to the effect of an external stimulus on the individual, and not apparently inherited, and two kinds which are hereditary.

J. T. CUNNINGHAM.

Chiswick, December 31.

Optical Observation of the Thermal Agitation of the Atoms in Crystals.

ACCORDING to the theory of specific heats developed by Debye, Nernst, and others, the thermal energy of a solid is made up of the energy of elastic vibrations in its material, the frequencies of such vibrations ranging from very small values up to a maximum limit determined by the ultimate molecular or atomic structure. On this view it is clear that at ordinary temperatures the density of a solid, and therefore also its refractive index if it be of transparent material, would vary arbitrarily from point to point about its mean value. In other words, a transparent crystal cannot be regarded as optically homogeneous even with reference to the comparatively long waves which constitute ordinary light. It follows that a certain proportion of the energy of a beam of light traversing the medium would be deviated laterally and appear as scattered light, the intensity of such scattering being a measure of the thermal agitation within the crystal. That some such effect must occur has already been pointed out by Sir Joseph Larmor (*Phil. Mag.*, vol. 37, p. 163, 1919), but no theoretical discussion of its magnitude appears so far to have been put forward. It has occurred to the present writer that the effect to be expected may be found in the following way:—If the principles of statistical mechanics and the equipartition of energy were applicable in the case of solids, precisely the same considerations which determine the molecular scattering of light in fluid media would enter here as well, and the scattering coefficient would be given by the Einstein-Smoluchowski formula

$$\frac{\pi^2}{18}\cdot\frac{RT\beta}{N\lambda^4}\cdot(\mu^2-1)^2(\mu^2+2)^2,$$

where β is the compressibility of the solid, μ is its refractive index, λ is the wave-length of the light, and R, T, N are the constants of the kinetic theory. It is known, however, that the heat-content of solids at the ordinary temperature is much less than that indicated by the equipartition principle, the deficiency being most marked for substances, such as diamond, having a high "characteristic temperature." The scattering coefficient given by the preceding formula must therefore be diminished in the ratio which the actual heat-content at the temperature of observation bears to the heat-content indicated by the equipartition principle. This correction-factor may be found from the experimental data for the specific heats at low temperatures given by Nernst, Lindemann, and others.

Calculations made in the way indicated above show that transparent quartz should scatter light $9\frac{1}{2}$ times as strongly as dust-free air at normal temperature and pressure. A scattering of approximately this magnitude in clear quartz was detected photographically by R. J. Strutt (now Lord Rayleigh) (Proc. Roy. Soc., vol. 95, p. 495, 1919), but was ascribed by him to inclusions which he assumed were present in the crystal. It is clear from what has been said above that the effect observed by him was actually due to the thermal agitation of the atoms in the crystal. The present writer has succeeded in demonstrating the scattering of light in clear quartz by direct visual observation. For this purpose a block of the crystal with smooth polished faces is immersed in a tank of clean distilled water to minimise surface-reflections and a converging lens is used to bring a beam of sunlight to a focus within the crystal. The blue track of the beam within the crystal may then be readily observed, and its intensity can be judged by comparison with the scattering of the beam in saturated ether vapour. The writer has had the pleasure of exhibiting the phenomenon to Sir W. J. Pope and other distinguished callers at his laboratory.

Transparent rock-salt which has a low characteristic temperature and shows a marked "Debye-effect" in experiments on X-ray reflection exhibits a very strong scattering of ordinary light. The increase of the scattering with rise of temperature may readily be observed with it.

C. V. RAMAN.

210 Bowbazaar Street, Calcutta, November 19.

A Fossil Buttercup.

WHEN we examine a catalogue of fossil plants, such as that for North America recently published by Knowlton, we are struck by the enormous number of recorded species, and readily receive the impression that the flora of former ages is quite well known. It is only when we make a more critical investigation that we perceive the great gap in our present knowledge. We do, perhaps, know a fair proportion of the trees and deciduous-leafed shrubs of a number of geological periods, but when we look for the herbaceous flora the limitations of our knowledge at once appear. Thus the Ranunculaceæ, an extensive family in the present North American flora, do not furnish a single definitely recorded fossil in the same area. Dawson in 1875 vaguely referred to a Thalictrum, without specific name, supposedly from the Eocene, but it is not to be taken seriously. Schenk thought the fossil genus Dewalquea presented a certain analogy with Helleborus, but it is now referred to quite another family. It is, of course, impossible to suppose that the Ranunculaceæ were absent from North America during Tertiary times; they simply must have escaped preservation or observation. To those who would see in the geological record a proof that herbaceous plants did not exist in the past, or were extremely rare, we can only reply that the record as it stands proves too much. To accept it at its face-value postulates the impossible. The general proposition that the herbaceous flora is, *on the whole*, more recent than the woody may be valid, and has much to recommend it.

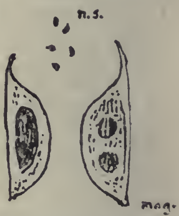

FIG. 1.—Achenes of *Ranunculus florissantensis.*

With regard to the Tertiary Ranunculaceæ of North America, we can fortunately rescue them from utter oblivion. Several years ago I found some slabs of Miocene shale at Florissant, Colorado, plentifully besprinkled with small dark fossil seeds. The exact locality is the railroad cut just east of the town.

These seeds were not studied at the time, but they are now seen to agree excellently with those of Ranunculus. They are, properly speaking, achenes, about 1·7 mm. long and 1 mm. broad, with a fairly long moderately curved beak. The general form approaches that of *R. pennsylvanicus*, but the achene is less robust. The fossil may be known as *R. florissantensis* n. sp. Ranunculus has a single seed in the achene. It has been definitely determined for *R. acris* at least that there is only one ovule. Our fossils, however, very distinctly show two, after the manner of Hydrastis. They were evidently small and dry at maturity, as in Ranunculus, and the most mature ones contain only one seed, dark and clearly outlined. It would be worth while to investigate the immature achenes of numerous species of Ranunculus to determine whether any start with two ovules, one aborting, as I have determined to be the case in Malvastrum. Heer has described a very similar Ranunculus seed (achene) from the Miocene of Oeningen in Baden.

The Absorption of Fluorescing Sodium Vapour.

ACCORDING to Bohr's theory concerning the origin of spectral lines, electrons in the atoms of sodium vapour under the influence of exciting D radiation are displaced from their normal 1·5 S orbit to the $2p$ orbits. During the return of the electrons to their normal orbit the so-called "resonance" radiation, first observed by Wood (*Phil. Mag.*, November, 1905, and "Researches in Physical Optics," part 2, p. 166), is re-emitted as fluorescent light. It has been suggested, therefore, by more than one observer (Foote and Meggers, *Phys. Rev.*, vol. 15, part 4, p. 323, and *Phil. Mag.*, vol. 40, p. 80, 1920) that fluorescing sodium vapour should absorb lines of the first and second subordinate series $2p_{,2} - ms$ and $2p_{,2} - md$. To test this point I have

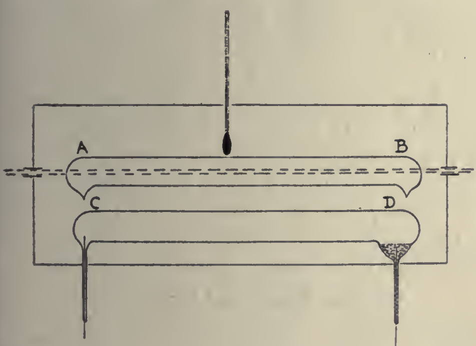

FIG. 1.

made use of the experimental arrangement outlined below. While a negative result was obtained, it seems worth while to record the trial, along with one or two suggestions for a more rigid test which I am not able to make at present.

A narrow beam of light from a Nernst lamp traversed the tube AB, some 25 cm. long, into which some sodium had been distilled in high vacuum (Fig. 1). By means of a lens the light was focussed on the slit of a Hilger constant-deviation spectroscope. Directly below the sodium tube was a sodium–potassium alloy "lamp" CD, a slight modification of the type recently described by Neuman (Proc. Phys. Soc. London, vol. 33, part 2, February 15, 1921). Both tubes were enclosed in an electric oven, by means of which they could easily be heated to 300° C. or higher. For two reasons it seemed to the writer that this lamp should be most suitable. In the first place, resonance can best be excited by very narrow spectral sources, and it had been shown that the light from the lamp consisted almost entirely of D lines of narrow width. Again, it could be operated at temperatures at which resonance is obtained in sodium vapour, so that it was possible to place the two tubes side by side in the same oven.

At temperatures ranging from 200° C. to 300° C., therefore, observations were made to see if there was any difference in the absorption spectrum when the exciting lamp was "on" and "off." The D absorption lines were easily visible, but not the slightest difference could be detected in the two cases. It is possible, however, that with an improved arrangement the absorption looked for might occur. The lines of the subordinate series most likely to be absorbed are the first members, which, however, are in the infra-red region and could not be observed visually. A much better test, therefore, would consist in photographing with dicyanine-stained plates in the hope of observing absorption of the doublet λ 8195 and λ 8184. Again, the intensity of the exciting light may not have been great enough to put a sufficiently large number of atoms in the desired state. This difficulty would be lessened by the use of two or three lamps, or possibly by adapting for use with sodium some such arrangement as was used by Füchtbauer (*Phys. Zeit.*, vol. 21, November 1 and 15, 1920) for observing resonance in mercury vapour. Finally, a longer absorption tube obviously would be more desirable. With improvements such as are suggested a much more rigid test could be made.

JOHN K. ROBERTSON.

Queen's University, Kingston, Canada,
December 17.

The Message of Science.

MR. W. ROBERTSON's letter in NATURE of January 5 is very timely. May I invite him and those his letter has interested or impressed to put into practice, in Middlesbrough or any other town, the "most practical suggestion of immediate value" he describes, with one important addition. Some of us have recently been striving to get his suggestion, thus widened and clinched, made operative in other British centres of population on behalf of the British Science Guild, the objective of which comprehends the exact duty Mr. Robertson acclaims and the methods of which in a new campaign have been dictated by a lively sense of provincial and metropolitan needs in the harnessing of science to important public tasks.

Our methods begin just where those of so many other people leave off. We ask local scientific societies and organisations and all who desire to make their special scientific equipment of use to their times to establish touch at once with the important local organisations and groups in which business men, administrators, and the occupational classes gather, and with them to consider "the progressive connecting of science with individual and corporate conduct," not in general, nor on another continent, but in their own towns (where facts can be known and methods tested), and in any of the problems on which much public time and public money have inevitably to be spent. That suffices for a beginning.

Many are feeling to-day that science should become, and can become, the "chief formative factor of modern

life." It will not become anything of the sort of its own volition, as scientific workers are not usually interested in broad problems outside their own particular fields, and those who have to be forced into the work are best out of it.

Functioning best begins with a real task, however difficult, before the particular community, preferably the first task which involves large sums of money, large expenditure of time and of energy, and considerable risk to human life. These tasks exist in bewildering profusion. The knowledge, without which they cannot even be stated correctly, exists also, and the prize of efficient performance cannot be won apart from its application. With human contact and the common sense of an adaptable race, tasks and knowledge can approximate each to each, and the first step in the unity of purpose which science can best bring to national life may be taken to-day in any city of the country. J. J. ROBINSON

(Secretary of the Parliamentary Committee of the British Science Guild).

Terrestrial Magnetic Disturbances and Sun-spots.

MAY I add a few remarks on Mr. Evershed's interesting letter on this topic (NATURE, December 29, p. 566), and supplementary also to my former letter (NATURE, October 27, p. 272). The protracted magnetic storm of May 12–21, 1921, after a lull on May 18, resumed an active phase on May 19–21. In my former letter I traced a sequence of magnetic disturbances, in connection with that of May 21, which extended to October 5. I may now add that the sequence has persisted until December 24, that is for 217 days, embracing eight synodical rotations of the sun, with a mean period of 27·13 days. The corresponding mean sidereal period would be 25·25 days, or 14·26° per day. This is Carrington's rotation period for latitudes 10° to 15°, and agrees closely with the sidereal period found by Mr. Evershed for the main series of disturbances from March 22 to September 29, 1921.

With regard to the series of disturbances from January 1 to November 21, 1920, which was also recorded at this observatory, Mr. Evershed deduces the equivalent solar period as 25·22 days, which is Carrington's value for spots about latitude ±10°. He remarks: "The slight difference of period compared with that obtained from the 1921 series does not make the evidence for these sequences less convincing." To my mind, in this particular case at least, it makes the evidence more convincing, because the mean latitude of the sun-spot group observed from December, 1920, to May, 1921, was about −6°, and, in fact, in the January appearance extended from 0° to −12° in latitude. In the case of the 1921 group, May 9–17, the mean heliographic latitude was +0·8°, but it extended north of the equator at least 5° in latitude, sufficiently in accord with a synodical rotation period of 27·13 days. A. L. CORTIE.

Stonyhurst College Observatory, January 2.

Reform of the Calendar: Mean Value of the Year.

I SEE there is to be a meeting at Rome in 1922 to consider questions concerning the calendar. I should like to direct attention to the fact, apparently little known—I, at least, have never seen it in any book—that if we make the year equal to 365 218/900 days we get a very good approximation, and one which can be applied by omitting leap-years at certain complete centuries, something like what is being done under the present Gregorian rule. If we say that "a century-year shall be a leap-year only if it gives a remainder of 2 or 7 when divided by 9," we have a rule which is much more approximate than the Gregorian rule, and one which has been followed *de facto* since 1582 (year of the Gregorian reform). The new rule would not differ in its application from the Gregorian rule before the year 2400. The Gregorian year, 365 97/400 days, differs from the true tropical year by 26 seconds; if the above modified rule were introduced the difference would be reduced to 2 seconds.

The "Encyclopædia Britannica" in the article "Calendar" mentions the value 365 31/128, which, no doubt, is very approximate (difference from true year 1 second), but depends on the awkward cycle of 128 years; and, besides, its application would mean a new break in the way of introducing, or rather suppressing, leap-years. ARTHUR ROSE-INNES.

Yokohama, November 27.

Units in Aeronautics.

PLEASE allow me to protest against Mr. A. R. Low's attack in NATURE of January 5, p. 12, on the "slug," which was not introduced by Prof. Bairstow, but probably by Prof. Fleeming Jenkin about thirty years ago. The slug does not lead to any evasion of Newton's laws any more than the poundal which was introduced by Prof. James Thomson. All such terms are useful so long as they are precisely defined and correctly understood; in recent years a distinguished German mathematician has been striving to introduce Prof. Thomson's "radian" in place of "Einheitskreisbogenlänge."

The contempt common amongst chemists and physicists towards so-called "engineers' units" is without justification. The chemist or physicist derives his unit of force from a definition of mass and acceleration, whereas the engineer derives his unit of mass from a definition of force and acceleration. The engineer's reason is that his problems come to him in terms of forces, and he wants his solution in the same units. Engineers on the Continent use the kilogram as the unit of force, and derive a metric slug in terms of the metre and second.

The ideologist is fond of so-called "absolute" units, but the physical meaning of Newton's or other laws is often made more clear when units are chosen conveniently. An ordinary man cannot realise a force of a dyne, though an insect might collapse under it; and while an astronomer measures distances in light-years, the peasant uses hours of walking and the spectroscopist μ. It is unlikely that the British or foreign working-man will ever ask for his beer in cubic centimetres: the unit is inconveniently small.

Chiswick, January 9. H. S. ROWELL.

A Curious Physiological Phenomenon.

THE phenomenon to which attention is directed by Mr. F. C. Dannatt in NATURE of December 22, p. 529, is an exceedingly interesting one, and may be the explanation of what occurs in "table turning" and "hat turning." Many have, no doubt, seen the hat, upon which many fingers are resting, move in a very peculiar manner, and it is difficult to believe that those who are engaged in the exhibition are not telling the truth when they declare that they are not aware that they are the cause of the movements. An essential element of the game is that the weight of the arms should be carried by the muscles, and it is interesting to learn that such strained conditions lead to involuntary muscular movements.

R. M. DEELEY.

Tintagil, Kew Gardens Road, Kew, Surrey, December 24.

Oceanography of the Gibraltar Region.

By DR. JOHS. SCHMIDT.

THE first month spent at sea by the *Dana* Expedition was occupied with investigations in the boundary area between the Atlantic and the Mediterranean—*i.e.* in the Bay of Cadiz, the Straits of Gibraltar, and the Western Mediterranean as far as Algiers. We had worked there before, in 1908–10, with the *Thor*. We were, therefore, not unacquainted with local conditions, and it was very interesting to compare the new investigations with the old. The expedition was particularly fortunate in being able, during this month, to enjoy the co-operation of Dr. J. N. Nielsen, who, from his participation in the *Thor* expeditions, is perhaps more familiar with the hydrography of these waters than anyone else. The remaining scientific staff of the expedition consisted of Messrs. P. Jespersen and A. V. Tåning, both ichthyologists and trained in the work of general marine biology; K. Stephensen, as expert in crustaceans; while the physical and chemical investigations were carried out by Messrs. J. Olsen and N. C. Andersen, the last-named being physician to the expedition.

Previous investigations—British, Danish, and Norwegian—have given us the main features (but no more) in the transfusion of water which takes place between the Mediterranean and the Atlantic. The most striking difference between Mediterranean and Atlantic water is in the salinity. Owing to the great evaporation, the water in the Mediterranean is of higher salinity than the Atlantic water—viz. more than 38 per mille (that is, 38 grams of salt in 1000 grams of sea-water) as against about 36–36·5. The less saline Atlantic water flows through the Straits of Gibraltar into the Mediterranean as a surface current. Deeper down, the Straits of Gibraltar are filled with salter water, which, coming from the Mediterranean, moves westward over the comparatively shallow threshold, in places only 400 metres down, formed here by the sea floor, which falls away steeply both to the east and west.

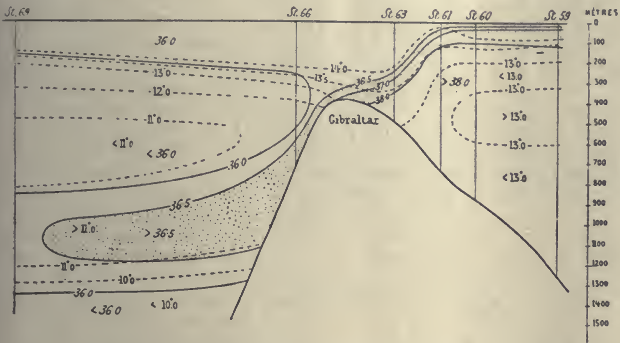

FIG. 1.—Showing isohalines (figures in italics) and isotherms. Hydrographical section through the Straits of Gibraltar from the investigations of the *Thor*, February, 1909. (Schmidt, Nielsen, and Jacobsen, 1910.)

On reaching the western edge of this ledge, the Mediterranean water pours down, like a veritable submarine waterfall, towards the depths of the Atlantic Ocean (Fig. 1). It does not, however, reach the bottom; being warmer, and therefore lighter, than the bottom water of the Atlantic, it spreads out as an intermediate layer in the Atlantic, which is recognisable in that it is of higher salinity than the water-layers above and below. J. N. Nielsen and F. Nansen have previously demonstrated the existence of this intermediate layer of Mediterranean water—or, more correctly, mixed water—right up to the west of the British Isles. At the stations of the *Dana* Expedition between Madeira and the Cape Verde Islands (Stations 1142, 1152, 1156, 1157, 1159) we found it at depths of about 1000–1500 metres, with a salinity naturally decreasing towards the south, but varying from about 35·7 per mille at Madeira, to about 35·03 near the Cape Verde Islands.

Up to now we have referred only to the outflow of Mediterranean water into the Atlantic. Fig. 2 gives a picture of the inflow of Atlantic water into the Mediterranean, based on the investigations of the *Dana* Expedition in the waters between Oran, Algeria, and the south coast of Spain. The figure represents a vertical section of the upper 400 metres of sea through our three stations 1119, 1120, and

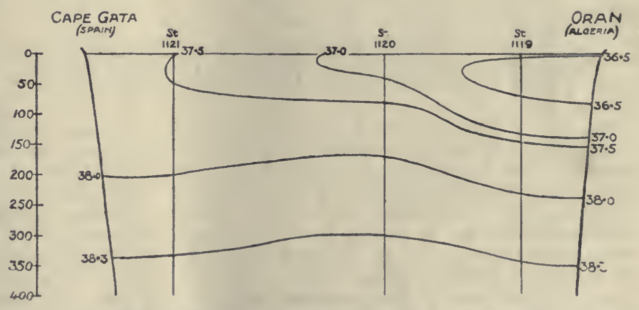

FIG. 2.—Hydrographical section through the westernmost portion of the Mediterranean as shown by the *Dana's* stations 1119, 1120, and 1121, about October 1, 1921. The isohalines for 36·5, 37·0, 37·5, 38·0, and 38·3 per mille salinity are shown. The depths are given in metres. The section shows that the inflowing Atlantic water (salinity less than 36·5 per mille) follows the coast of Africa.

1121, showing the depths and the course of the isohalines. It will be seen that unmixed Atlantic water, of a salinity less than 36·5 per mille, flows in along the north coast of Africa. Midway (Station 1120) we find a slight, and farther north, off the coast of Spain (Station 1121), a somewhat more pronounced, admixture of Mediterranean water. From this it must be concluded that the velocity of the east-going current is at its highest close in to the African shore, and lowest off the coast of Spain, which is also in accordance with fact. The section further shows that the inflow of Atlantic water is a comparatively superficial phenomenon, almost pure Mediterranean water being found at a relatively slight depth.

For nearly a week at the beginning of October the *Dana* remained at Gibraltar in order to study the inflow of Atlantic water and the accompanying migration of pelagic organisms through the Straits. On several occasions continuous investigations were made, as, for instance, from 9 p.m. on October 8 to 6 a.m. on October 10, when series of water samples, with observations of temperature, were taken every three hours; in the intervals between hydrographical observations fishing with pelagic nets was carried out at various depths. All these investigations were made at the same spot, about the middle of the Straits, with Tarifa, in Spain, to the west-north-west. The investigations showed that both physical and biological conditions varied greatly in the course of the twenty-four hours. Temperature and salinity, for instance, did not remain constant at a given depth throughout that time. Fig. 3 shows how water of 14° C. and 37·4 per mille salinity—characteristic values for temperature and salinity of mixed Atlantic and Mediterranean water—changes its level within the twenty-four hours. It will at once be noticed that the changes are periodical, and a closer investigation of the times indicated places it beyond doubt

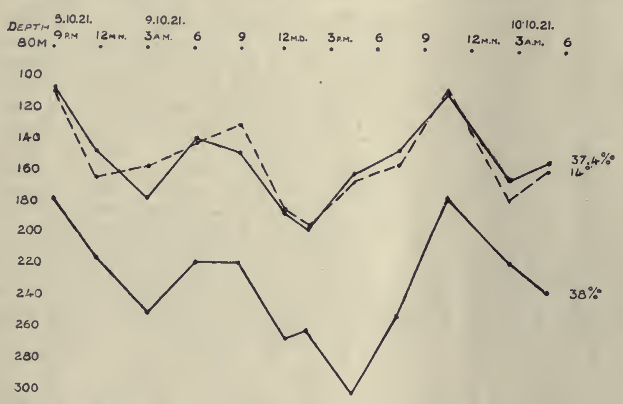

FIG. 3.—Straits of Gibraltar: St. 1138, lat. 35° 59′ N., long. 5° 30′ W. Continual observations at the same spot from 9 p.m. October 8 to 6 a.m. October 10, showing periodical shifting of the level at which salinities of 37·4 and 38·0 per mille and a temperature of 14° C. are found during the period of observation. The depths are given in metres.

that we have here to deal with a tidal phenomenon, albeit the magnitude of the alteration in level would appear to be also dependent upon other factors, such as the direction and force of the wind.

A comparison of the contents of the pelagic nets throughout the night at our station off Tarifa proved highly interesting, but raised questions which I soon perceived were to be solved only by a far longer stay at this point than the *Dana* could afford. I will take one example. A net drawn horizontally at about 150 metres' depth on October 8 for two hours from 10.15 p.m. brought up about 80 litres of matter, consisting almost exclusively of a siphonophore (Diphyes). Towards morning Diphyes had disappeared, the contents of the net from 150 metres' depth then consisting chiefly of Salpæ and a schizopodous crustacean. The same phenomenon was repeated next night: first scarcely anything but Diphyes, and later on almost exclusively Salpæ. Our hauls thus showed that the depth at which Diphyes and Salpæ are found is subject to alteration, but the question then arises whether such alteration is due to active movement of the organisms in question, or to a purely passive shifting answering to the change in level of the water layers effected by the action of the tides.

A comparison of the pelagic fauna on both sides of the Straits of Gibraltar was likewise of much interest. As the main result it may be stated that several species were common to both areas, while others were found only west of Gibraltar. Among the latter may be quoted, of fishes: *Argyropelecus Olfersi*, *Vinciguerria Sanzoi*, *Myctophum laternatum*, and *M. Valdivia*, with various murænoid larvæ (*Leptocephalus Synaphobranchi pinnati*, *L. latissimus*, *L. lanceolatoides*, etc.). In contrast to these I may mention the larvæ of the common freshwater eel (*Leptocephalus brevirostris*), which pass through the Straits of Gibraltar in enormous numbers. This phenomenon was one of particular interest to the expedition, and I hope to be able to say more about this to readers of NATURE later on. Here again we are faced with new problems. Why, for instance, should certain pelagic species stop just outside the Straits of Gibraltar, and others, which out here may be taken in the same haul with the former, not be found in the Mediterranean? Are they killed immediately on entering the Mediterranean by the natural conditions prevailing there, or are they able in some way, despite their pelagic habit, to maintain their position—possibly by means of vertical migrations? Various features would seem to suggest that it is not sufficient to regard the problem solely from the point of view of direction of current as found by

the use of a current meter, but that other factors also come into play. Otherwise it would be difficult, for instance, to understand how certain pelagic species of fish (*Myctophum glaciale* and *M. Dofleini*, *Stomias boa*, etc.) can at all seasons occur in far greater quantities—have a maximum of density—in the Alboran Sea (the westernmost part of the Mediterranean, between Spain and Morocco) than either west or east of there, despite the fact that the surface layers are in constant movement towards the east. This is actually the case, as was first shown by A. V. Tåning and Vilh. Ege on the basis of material from the *Thor* expeditions. The *Dana* Expedition has proved the same thing. Comparatively few specimens occur west of Gibraltar and east of Oran, but in the Alboran Sea itself great quantities of all three species were found, so that the contents of a single net might show, for instance, more than 1500 specimens, especially *Myctophum glaciale*.

In conclusion I cannot refrain from emphasising the extreme importance an intensive study of the Straits of Gibraltar and adjacent waters would have for general—physical and biological—oceanography. When, at the commencement of October, I was obliged to leave this area in order to take up the other tasks allotted to the *Dana* Expedition, it was with the conviction that the expedition would in all probability have been able to do more for the cause of oceanography in general by keeping station at Gibraltar during the ten months we have for work, than by cruising about the ocean. Being so convinced, I venture to hope that British naturalists may soon take up this important task, which Great Britain, with Gibraltar as a base, has unique opportunities for dealing with. A research vessel stationed at Gibraltar would take but half an hour to arrive on the scene of operations, the meeting-place of two deep seas. The saving in time and coal, and the unparalleled opportunities of utilising all favourable weather conditions for oceanographical work, are self-evident.

(On board the *Dana*, at San Vicente, Cape Verde Islands, November 1, 1921.)

Photographic Studies of Heights of Aurora.

By Dr. C. Chree, F.R.S.

THE two publications referred to below,[1] by Prof. Carl Störmer, of Christiania, merit the attention of all interested in the physics of the atmosphere. As is generally known, Prof. Störmer discovered a satisfactory method of measuring the height and position of aurora by means of photographs taken simultaneously at the two ends of a long base. The photographs include two or more stars, the exact positions of which in space are ascertainable, the precise time of taking the photographs being known. The difference between the positions of the aurora relative to the stars in the two photographs enables the necessary calculations to be made.

The first memoir gives a very full account of photographs taken in the spring of 1913 at two Norwegian stations, Bossekop (B.) and Store Korsnes (K.), 27·5 km. apart, near latitude 70° N. Some of the results have been already discussed in a series of papers enumerated on p. 7, which have appeared in different publications, especially *Terrestrial Magnetism and Electricity*, the *Astrophysical Journal*, and the Paris *Comptes rendus*. But the present memoir, besides summarising these, contains much new matter. In chaps. 1 and 2, pp. 8–37, there is a description of the apparatus and equipment and of the methods of observation. This is intended to be supplementary to descriptions already given, but describes various improvements and simplifications. Chap. 3, pp. 38–156, is a complete journal in chronological order of all the 336 pairs of photographs discussed. Besides the date and hour and time of exposure, values are given of the parallax of each selected auroral point (*i.e.* the angle subtended at the point by the 27.5-km. base), its astronomical co-ordinates (altitude and azimuth), and several calculated data, including the height of the point above the ground, and the distance from Bossekop of the point itself and of the corresponding point on the earth's surface vertically under it. The vertical heights vary from 87 to 323 km., the horizontal distances from Bossekop from 5 to 780 km. Some of the more notable auroras are discussed in considerable detail. The 336 pairs of photographs appear in plates 1 to 28, each plate containing twelve B. (Bossekop) and the corresponding twelve K. (Korsnes) photographs. To each pair of photographs there answers a diagram showing the stars used in the calculations, the positions of the auroral points, usually distinguished by numerals, and dashed lines to represent the parallaxes.

We reproduce two pairs of B. and K. photographs. One (Fig. 1) represents an auroral curtain in which twenty-one points were measured. The nearest point (towards the apparent tops of the photographs) was at a horizontal distance of 99 km. from Bossekop, the most remote point (near the lower left-hand corner) at a distance of 265 km. The heights measured varied from 90 to 130 km. Fig. 2 represents a band having the right-hand edge exceedingly sharp and luminous. The twelve points measured are shown in the key diagram (Fig. 3). Their heights varied only from 102 to 108 km. The horizontal distances from Bossekop of points 1 and 12 were respectively 61 and 178 km., and their parallaxes were 13·1° and 7·7°. The stars used were α, β, and θ Aurigæ. C_1 and C_2 represent the positions relative to the stars of the centres of the plates for Bossekop and Korsnes. The other details as to the stars refer

[1] Carl Störmer: "Rapport sur une expédition d'aurores boréales à Bossekop et Store Korsnes pendant le printemps de l'année 1913." *Geofysiske Publikationer*, vol. 1, No. 5. Pp. 269+104 plates. (Kristiania, 1921.)
"Exemples de rayons auroraux dépassant des altitudes de 500 kilomètres au-dessus de la terre." *Geofysiske Publikationer*, vol. 2, No. 2. Pp. 5+2 plates. (Kristiania, 1921.)

to the Bossekop photograph. The arrow-heads radiating from each star show the directions of the star's declination (δ) and altitude (h) circles and of the auroral parallax (p). The numerals 39, 43, 46 represent degrees of altitude. The azimuths of the stars, 180°–89·5°, etc., are also shown. The dotted lines represent the parallaxes in magnitude and direction.

K. B.

FIG. 1.—Auroral curtain photographed at Korsnes and Bossekop.

B. K.

FIG. 2.—Auroral band photographed at Bossekop and Korsnes.

The 336 key diagrams occupy plates 33 to 87. Finally, there are charts numbered 1 to 32, included in plates 90 to 104, which show the geographical positions of the points on the earth vertically under all the auroral points dealt with. The observational data are thus presented in an extremely systematic fashion. Chap. 4, pp. 157–212, includes a mathematical investigation of the variation in the inclination of the trajectory of an electrified corpuscle to the direction of magnetic force, the magnetic field having a potential. In the applications the earth's field is supposed to be given with sufficient accuracy by the first-order Gaussian terms. The corpuscle is supposed to have emanated from the sun, and its course is considered after it has come to within 500 km. of the earth's surface. The inclination of the trajectory to the magnetic lines of force tends to increase as the corpuscle approaches the earth. If the angle attains to 90° the corpuscle retreats. The energy may be absorbed while the corpuscle is approaching or while it is retreating, or some may remain after the retreat has carried the corpuscle outside the atmosphere. What happens is

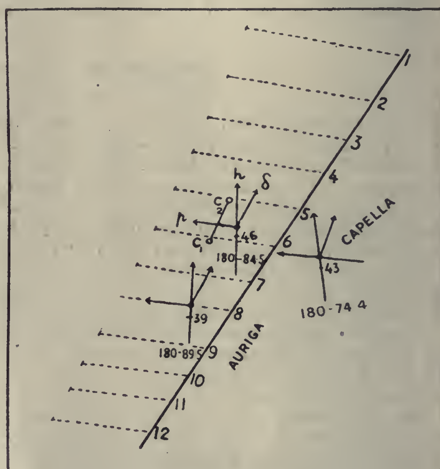

FIG. 3.—Measurements of points on Fig. 2.

shown to be largely dependent on the constitution of the atmosphere. The author assumes that throughout the troposphere, the upper limit of which is put at 10·5 km., air is constituted exactly as at the earth's surface. But higher up in the stratosphere the several constituents, nitrogen, oxygen, argon, neon, helium, krypton, xenon, and hydrogen, behave independently. The author essentially follows Mr. Jeans, rejecting Wegener's hypothetical gas geocoronium. According to his calculations, p. 173, helium is the most important gas between heights of 110 and 200 km., hydrogen preponderating at greater, and nitrogen at lower, levels. These are practically the only gases that count when we consider how far down an auroral ray can come in the atmosphere. Separate calculations are made of the absorption of cathode and β-rays on one hand, and of α-rays on the

other. A number of special cases are worked out for both positive and negative rays, and the luminosity at different heights is considered.

Chap. 5, pp. 213–222, comparing theory with observation, gives a brief analysis of the observed heights and contains some historical matter. The α-ray theory of aurora is credited to Prof. Vegard, who has now, however, abandoned it. The author's own conclusions seem, on the whole, in general accord with those now held by Vegard. He considers that the luminosity phenomena of aurora cannot be explained on the α-ray hypothesis except for what he calls "plaques pulsatoires." The most likely sources of all other auroras, he thinks, are cathode rays.

On pp. 221–22 is an interesting statement of what Prof. Störmer takes to be the auroral problems now calling for attention. The observational problems include height measurements in the Arctic and Antarctic, and the investigation of the auroral spectrum at different levels. The first theoretical problem remaining is to take account of the mutual electro-magnetic actions of the corpuscular currents, as well as of the action of the magnetic fields of the earth and sun. "On pourra alors . . . étudier jusqu'à quel point les objections de Shuster (Schuster) relatives à des faisceaux cathodiques dans l'espace sont bien fondées ou non." A second theoretical problem is to apply the knowledge we may gain of the auroral corpuscles to the study of solar physics.

The second paper by Prof. Störmer relates to auroral measurements made during a great magnetic storm on March 22–23, 1920. Use was made on that occasion of seven stations giving bases varying in length from 26 to 250 km. Of the heights measured, six exceeded 500 km., one being 607 km. The plates attached to the paper are enlarged negatives of the photographs obtained. The photograph reproduced here (Fig. 4)

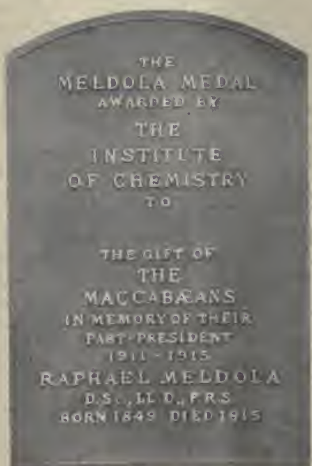
Fig. 4.—Aurora during the magnetic storm of March 22–23, 1920.

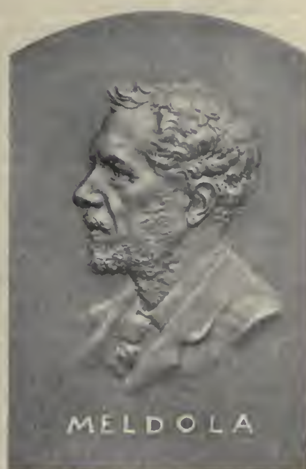
is a positive, which we owe to the kindness of Prof. Störmer. The demonstration of the existence of a sensible atmosphere at heights exceeding 500 km. is a notable event.

The Meldola Medal.

Raphael Meldola was a man of remarkable versatility, eminent to an unusual degree in several sciences—chemistry, biology, entymology, astronomy—and of unbounded energy. How broad his sympathies and interests were, and how distinguished his services, should be sufficiently apparent from the fact that he was elected to the presidential chairs of the Essex Field Club, the Entomological Society, the Chemical Society, the Society of Dyers and Colorists, the Society of Chemical Industry, and the Institute of Chemistry. Apart from the distinctions connected with his scientific pursuits, Meldola was held in high honour among his own people as president of the Maccabæans, a society in London consisting mainly of Jewish professional men devoted to the promotion of the interests of the Jewish race.

That society has instituted a medal in order to perpetuate his memory, and has arranged with the council of the Institute of Chemistry that the





The Meldola Medal.

Meldola medal be presented annually for the most meritorious chemical work of the year ending on the last day of December preceding the award. The award is not to be restricted to any particular branch, but the administrators, who are the council of the institute and a member of the Maccabæans appointed by their committee, will have primary regard to work done in analytical chemistry. The award, however, is restricted to British subjects of not more than thirty years of age at the time of the completion of the work—a condition seldom, if ever, attaching to awards of this kind. It is intended to afford encouragement to young investigators and to imply recognition of high merit—which is more frequently accorded in later life to those who have long achieved distinction. The medal, which is in bronze and is here illustrated, has been designed and executed by Mr. Frank Bowcher.

The council of the Institute of Chemistry hopes that the first award may be made at the annual general meeting of the institute on March 1 next. Chemists are invited at any time prior to Friday, January 20, to direct attention to published work of distinctive character, preferably in analytical chemistry, carried out during 1921. Such communications should be headed "Meldola Medal," and should be addressed to the registrar of the institute, 30 Russell Square, W.C.1.

Meldola died on November 16, 1915, and many will remember that in 1917, by subscription among his friends, two portraits of him, by Mr. S. J. Solomon, R.A., were presented to the Royal Society and the Institute of Chemistry. The medal affords an additional fitting tribute to one of the most notable men of science of our time.

Obituary.

DR T. A CHAPMAN, F.R.S.

DR. THOMAS ALGERNON CHAPMAN died at Reigate on December 17 last after a long period of failing health, in the eightieth year of his age. His father, Dr. Thomas Chapman, of Glasgow, was in his day an entomologist of high repute, and the life-long devotion of the son to the study of insects commenced at an early age. After graduating in medicine (with honours) and surgery at Glasgow and Edinburgh, Dr. Chapman was for a time resident physician and surgeon to the Glasgow Royal Infirmary, and in 1866 he received an appointment to the Joint Counties Asylum at Abergavenny. He afterwards became Medical Superintendent to the County and City Asylum of Hereford, and during his tenure of this office, from which he retired in 1895, he contributed several important papers to the *Journal of Mental Science*.

A keen and successful collector, and a delightful companion in the field, Dr. Chapman was, in addition, one of the most philosophical of naturalists and the most accurate and painstaking of observers. His long series of entomological memoirs—the Royal Society's Catalogue and the "Zoological Record" enumerate more than 250 separate papers published by him from 1868 onwards in the current magazines and the Transactions of the Entomological Society of London—regarded as a whole, takes rank among the most important contributions to the science of entomology by a single individual in recent years. Some of his early papers deal with the life-histories of certain wood-feeding Coleoptera of great economic importance and interest, but the great bulk of Dr. Chapman's work relates to the Lepidoptera, chiefly from the bionomic and taxonomic aspect. Of late years he devoted considerable attention to the biology of sawflies, and the last paper from his pen on this subject appears in the *Entomologists' Monthly Magazine* for January.

Among the most important of Dr. Chapman's memoirs are those on the value of pupal characters in the classification of the Lepidoptera; on the life-history of the Micropterygidæ, and the true relations of these singular insects, for which he recently proposed a new order, the Zeugloptera; and the life-histories, in some cases previously unknown, of many species of British and European Lycænidæ or "blue" butterflies, and the association of their larvæ with ants and other insects, the material for these researches being acquired in many visits to the Alps and other parts of the Continent in his later years. The solution of the mystery of the larval and pupal life of *Nomiades arion*, for so many years an entomological enigma, is in large measure due to his acumen and patient observation.

Dr. Chapman became a fellow of the Entomological Society of London in 1891, served repeatedly on the council, and was vice-president of the society on no fewer than four occasions; but, to the great regret of his colleagues, he could never be induced to assume the office of president, which was long open to his acceptance. He joined the Zoological Society in 1898, and in 1918 he was elected a fellow of the Royal Society. His genial and engaging personality will be greatly missed by his wide circle of friends and fellow-workers, and very few men were more highly and deservedly esteemed in life or are more deeply regretted in death. J. J. W.

IT is announced in *Science* that PROF. HENRY TURNER EDDY, professor emeritus of mathematics and mechanics in the University of Minnesota and dean emeritus of the graduate school, died on December 18 last at the age of seventy-seven years. Prof. Eddy was professor of mathematics, astronomy, and civil engineering in the University of Cincinnati for sixteen years, and went to the University of Minnesota in 1894 as professor of engineering and mechanics. Later he became professor of mathematics and mechanics. He served both as secretary and vice-president of the American Association for the Advancement of Science, and was also a member of several other learned societies in America.

Notes.

ALL friends of humanity will welcome with a profound sense of relief the intimation that the representatives of Great Britain, France, Italy, Japan, and the United States, assembled at the Washington Conference, have agreed to the American proposal to prohibit the use of poison gas in warfare. As Mr. A. J. Balfour pointed out, in announcing the adherence of Great Britain, Mr. Root's resolution was, in effect, a re-affirmation of international law as it existed prior to 1915, when it was deliberately violated by Germany. He was conscious, as was M. Sarraut, the representative of France, that the exercise of authority in banning the use of an abhorrent method of warfare was, under present conditions, scarcely practicable, and that whilst the agreement would serve to bind the Five Powers, it would not relieve nations from the necessity of preparing themselves against the use of gas by an unscrupulous enemy. We could not afford to ignore the lesson of April, 1915. The position thus reached by the Washington Conference is as satisfactory as could be expected. It is, in fact, all that was practicable, and it will be welcomed by all the Powers comprising the League of Nations. The issue now rests with Germany. But the moral effect of the action of the Conference will not be lost upon the world.

SIR DAVID PRAIN will shortly retire on account of age from the post of Director of the Royal Botanic Gardens, Kew, which he has held since 1905, and the First Lord of the Treasury has appointed as his successor Dr. A. W. Hill, who has been Assistant Director of the gardens for the last fourteen years, and was previously 'fellow' and 'dean' of King's College, Cambridge, and University lecturer in botany. Sir David Prain was born in 1857, and entered the Indian Medical Service in 1884, when he was almost at once seconded for service in the Botanic Garden at Sibpur, Calcutta, as curator of the herbarium, in 1898 succeeding the late Sir George King as superintendent. During this period his activities included the duties of professor of botany in the Calcutta Medical College, Director of the Botanical Survey of India, a trustee of the India Museum, and fellow of the Calcutta University. Upon the retirement of Sir William Thiselton-Dyer in 1905 from the directorship of the Royal Botanic Gardens at Kew, Sir David Prain was appointed his successor, and he has worthily maintained the high traditions of his post, the highest and most important of its kind in the British Empire. He has also been president of the Linnean Society of London (1916–19) and treasurer of the Royal Society since 1919, besides serving on numerous boards and committees of biological associations, where his well-balanced judgment and large experience have made him welcome. On entering on his duties at Kew he found them so exacting that his favourite botanic studies have been curtailed; with his coming release from official labours he will, no doubt, be able to devote himself to original work once more. Dr. Arthur Hill, who succeeds to the office of Director, has travelled in South America and tropical Africa; he has also been largely responsible for the laying-out of British cemeteries in France and Italy.

AN expedition, consisting of Prof. J. W. Gregory, of Glasgow University, and his son, Mr. Christopher J. Gregory, which has for its primary object the investigation of some features in the mountain structure of north-western Yunnan and western Szechuan, expects to leave for Burma at the end of March. The area is one of special geological and biological interest. It includes some mountains of which the height varies, according to the available information, from 20,000 to 25,000 ft.; and as these mountains occur in line with the Himalaya and the mountains south of Assam, it has been suggested that they represent a prolongation of the Himalaya and are continuous through China with the main mountain lines of north-eastern Asia. This view is opposed to the interpretation by von Richthofen that the mountains of this part of China belong to a pre-Himalayan system which they cross almost at right angles, and that the continuation of the Himalayan folds bends back through western Burma and is continued by the mountains on the southern edge of the Eastern Archipelago. It is hoped to obtain evidence for the solution of this problem, and also in reference to the remarkable parallelism of the three great rivers which discharge from south-eastern Tibet. The area is of biological interest in connection with the geographical distribution of the fauna and flora of south-eastern Asia. Some zoological and botanical collections will be made which it is hoped will be worked out in the British Museum of Natural History and in the India Museum, Calcutta. The expedition will travel *via* Rangoon, and hopes to start from Bhamo, near the north-western frontier of Burma, at the beginning of May.

THE council of the Geological Society has this year made the following awards:—Wollaston medal, Dr. A. Harker; Murchison medal, Dr. J. W. Evans; Lyell medal, Dr. C. Davison; Wollaston fund, Dr. L. J. Wills; Murchison fund, Mr. H. Bolton; and Lyell fund, Mr. A. Macconochie and Mr. D. Tait.

BEGINNING on January 26, we have arranged to issue a monthly supplement giving the titles of new books on science and technology published at home and abroad. Publishers have been invited to send us the titles of such additions to their catalogues, and it is hoped to make the lists an index to the chief scientific works issued. Any assistance which may be offered in order to make our lists complete will be welcomed.

AN Exchange telegram published in the *Daily Mail* on Monday announced that after a visit to Mount Kosciusko, the highest in Australia, Sir T. Edgeworth David and Profs. Skeats and Richards have confirmed the discovery in 1893 that the summit of that mountain was formerly covered by glaciers. The

new observations show that the glaciation was contemporary with the extinct giant wombat and other giant marsupials, which there is much evidence to show lived in south-eastern Australia when moister climatic conditions prevailed. The date of this glaciation is estimated by Sir Edgeworth David and his colleagues, according to the report, as 100,000 years ago.

At a meeting of the provisional council of the New Zealand Astronomical Society, held at the Hector Observatory, Wellington, on November 15 last, the following officers were elected:—*President:* Dr. C. E. Adams. *Vice-Presidents:* Hon. Sir Francis Bell, Prof. E. Marsden, Mr. T. Allison, and Dr. C. Munro Hector. *Secretary:* Prof. D. M. Y. Sommerville. *Treasurer:* Mr. C. G. G. Berry. *Editor:* Mr. A. C. Gifford. *Council:* Mr. J. C. Begg, Hon. Mr. Justice Chapman, Prof. C. Coleridge Farr, Mr. E. G. Hogg, Capt. G. S. Hooper, and Mr. J. T. Ward.

Under a provision of the Sundry Civil Act of March 4, 1921, Government Departments of the U.S.A. were required to suspend publication of all periodicals except those approved by Congress by December 1, 1921. A resolution empowering the Congressional Joint Committee on Printing to authorise the continuance or discontinuance of these periodicals, among them the *Journal of Agricultural Research*, passed the Senate, but did not come to a vote in the House before the adjournment of the last session of Congress. The *Journal of Agricultural Research* has, therefore, been suspended until its continuance is authorised by Congress.

On Tuesday next, January 17, at 3 o'clock, Dr. F. H. A. Marshall begins a course of two lectures at the Royal Institution on "Physiology as Applied to Agriculture"; on Thursday, January 19, Mr. Seton Gordon gives the first of two lectures on "Mountain Birds of Scotland" and "Sea-birds and Seals"; and on Saturday, January 21, Dr. Charles Macpherson, organist of St. Paul's Cathedral, commences a course of two lectures, with musical illustration, on "The Evolution of Organ Music." The Friday evening discourse on January 20 will be delivered by Sir James Dewar on "Soap Films and Molecular Forces," and on January 27 by Viscount Burnham on "Journalism."

The *Echo de Paris* is to be congratulated on the success of the subscription it raised to enable the octogenarian physicist Edouard Branly to continue his experimental work. Like many scientific men, Branly never sought commercial profits out of his discoveries, but the French public was unaware of the straits to which he had been reduced. It is now announced that the Branly Fund exceeds 200,000 francs (about 4000*l.*). Branly was the first to point out in 1890 that the electric resistance of a mass of metallic powder changed enormously when an electric spark took place in its neighbourhood. The resistance generally diminishes, but in a few cases—for instance, with peroxide of lead—it increases when the spark ensues. This was the principle of the earliest form of coherer which in the early days gave such an impetus to radiotelegraphy.

The first meeting of the Society of Telegraph Engineers was held on February 28, 1872, and the council of the Institution of Electrical Engineers (originally the Society of Telegraph Engineers) is arranging to commemorate the fiftieth anniversary of the meeting. On February 21 at 4 p.m., and on February 22 at 8.30 p.m., Prof. J. A. Fleming will deliver a popular lecture (to which admission is by ticket) on "Michael Faraday and the Foundations of Electrical Engineering." The annual dinner of the institution will be held on February 21, at 7 p.m., at the Hotel Cecil, and in the afternoon and evening of February 23 several members of the institution and others closely connected with the early development of electrical engineering will give short discourses on their reminiscences and experiences during the early history of the electricity supply industry. The speakers will deal both with matters of scientific and technical interest, and also with the effect of legislative action on the progress of the industry.

Influenza seems to be asserting itself with sufficient intensity to call for caution, especially on the part of the individual attacked, although at present the epidemic has not become sufficiently violent to cause alarm. The Registrar-General's weekly returns show that for the ninety-six great towns of England and Wales, including London, the deaths from influenza in the last six weeks have increased from 80 to 418, and in London alone the deaths from this cause have increased from 26 to 151. Fifty-nine per cent. of the deaths in London have occurred at ages above forty-five, whilst between twenty and forty-five years of age the deaths are 27 per cent., and below twenty years of age only 14 per cent. The age-incidence of death in the present epidemic differs from that in the severe epidemic of 1918–19, which for the most part attacked the able-bodied; the present attack has reverted to the incidence shown by the earlier epidemics after 1890. In the six weeks the deaths from pneumonia have nearly doubled, whilst deaths from bronchitis have remained fairly steady. With the abnormally mild weather in December the disease increased, which was a common feature with earlier epidemics, and it is to be hoped that the drop in temperature experienced in the early days of 1922 will lessen the severity of the attack.

Temperature in the past year was almost as abnormal as the rainfall, and November was the only month at Greenwich with the mean temperature below the average, whether compared with the normal for sixty-five years, 1841–1905, or with the normal for thirty-five years, 1881–1915, used by the Meteorological Office. The temperatures are given in Fahrenheit, and are chiefly from civil-day observations at Greenwich. The warmest month was July, with a mean of 68·5°, which is 4·8° above the average for sixty-five years, but both in January and October the excess of temperature was rather more than 7°. In November the

deficiency was 3·4°, but in December the excess was 4·7°. The mean temperature for the year was 52·8°, which is 2·7° in excess of the yearly normal; this is the highest mean annual temperature on record since 1841, the next highest being 52·0° in 1868 and 1911. In July the mean of the maximum, or highest day temperatures, was 81·6°; there have been only two years since 1841 with a higher mean maximum in July, 81·8° in 1859 and 82·0° in 1868. In January the mean maximum was 50·0°, and January, 1916, with a mean maximum 50·4°, is the only January with so high a mean maximum since 1841. The mean minimum in January is the highest on record. The mean for October, 57·6°, has never previously been equalled at Greenwich, and the high temperatures at the commencement of the month were most abnormal. For the British Isles generally the mean temperature for each month from January to April and in July, September, and October was above the normal in all districts, and in England and Wales there was an excess every month from January to October, except for August, in North-West England, where it was in agreement with the average. The mean excess of temperature for all districts in the British Isles, except the North of Scotland and the English Channel, for the ten months, January to October, was 2·6°; in January the excess was 5·2°, in July 4·3°, and in October 6·9°.

THE United States National Museum (Proc., vol. 59) has published a descriptive catalogue of its collection of Buddhist art, compiled by Mr. I. M. Casanowicz. The collection is large, but it does not seem to possess many objects valuable for their antiquity or artistic beauty, the best being a Japanese bronze statue of Buddha, dated 1648. There is also a good collection of rosaries, examples of magical appliances, and objects used in worship. Mr. Casanowicz has given an interesting introduction on Buddhism and its developments. The pamphlet deserves the attention of all those who are interested in the subject.

THE Journal of the Royal Anthropological Institute, part 1, for 1921, prints the presidential address delivered by Sir Everard im Thurn, which gives an interesting historical sketch of the relations between Europeans and the natives of the South Sea Islands after they were discovered. The state of savagery in which the natives were found does not imply fierceness: they were wild and uncontrolled in so far as they had not been subjected to what we call "civilisation," but they had developed for themselves a certain degree—in many cases a very high degree—of culture. The writer sums up his conclusions thus: "The Islanders were, when Europeans first went among them, not a savage, *i.e.* a fierce race, but were highly cultured, if self-cultured, people, but entirely uncivilised; they were at first puzzled what to make of the civilised, or quasi-civilised, people who went among them, and they only became repellent when they were habitually injured by their visitors."

THE educational work of the Commercial Museum of Philadelphia, as decribed by its curator, Mr. C. R. Toothaker, in Bulletin No. 13 (1920) of the United States Bureau of Education, is partly for business men and partly for the rising generation. Aid is given to the former by the foreign trade bureau of the museum, which publishes two journals, one of them in separate Spanish and English editions. Schools are provided for by official guidance to a study of the exhibits, daily lectures to visiting classes on subjects chosen by the school-teachers, lectures to teachers and others, loan lectures with lantern-slides sent to schools outside Philadelphia, and school collections given, not lent, to the schools of Pennsylvania. Full details of these last are given in this well-illustrated pamphlet.

THE recently published annual report of the Yorkshire Philosophical Society for 1920 reminds us that with 1922 the society reaches its centenary. It sprang from the suggestion that a museum should be founded to receive the bones just discovered in the Kirkdale Cave. Famous men have been connected with the society. It was the parent of the British Association in 1831 and of the Museums Association in 1888, while in local archæology it has done, and is doing, admirable work. Under the present keeper of the museum, Dr. Collinge, the zoological collections are being put in good order, and Mr. J. Hetherton has lately placed a wood of considerable area at the disposal of the society for use as a bird sanctuary. The geological collections contain many valuable fossils, and the report concludes with "Notes on the Later Tertiary Invertebrata" of these islands by the veteran Mr. Alfred Bell; most of the species are in the society's museum.

THE last annual report of the National Museum of Wales records some advance in completing the western section of the new building. The reserve galleries and basement are now occupied, and the keepers of art, botany, and zoology, with their staffs, are installed in their new quarters, while the department of geology has temporary accommodation. These departments are, however, hindered by lack of museum furniture, for which the available funds are insufficient. The museum worthily acts up to its title of "National," co-operating with all relevant bodies in the Principality, with mine-owners, quarry-owners, and industrial firms, and in particular with the faunistic survey of the County of Glamorgan and the local education authorities. A number of accessions of local interest, as well as many others, are recorded by all the departments. It is not in man to command financial support, but Dr. Hoyle and his able staff undoubtedly deserve it.

THE geological model of the Bristol district which has recently been placed in the Bristol Museum and Art Gallery depicts the relief and the geological outcrops of the district on a horizontal scale of 3 in. to 1 mile and a vertical scale of 1 in. to 500 ft. An explanatory guide to this relief map has been prepared by Prof. S. H. Reynolds. The pamphlet includes a description of the present land surface and a sketch of the geological history designed to explain the

origin of the chief physical features. A short account of the distribution of the geological formations is also given, and this is followed by a section which describes the roads and railways of the district in their relation to the surface relief. The pamphlet should prove indispensable to those students and teachers of geography and geology who have access to the model.

FROM the "Report on the Zoological Service for the Year 1920" we learn that the Giza Zoological Gardens have been restored to their pre-war condition of cleanliness. The number of visitors during that year was greater than in any previous year. A special feature of these gardens is the thousands of birds in a state of complete liberty which frequent the grounds, and we are glad to note that the numbers of cattle egrets, little egrets, and hoopoes which have nested there are increasing. The new building of the Giza Zoological Museum was opened in 1920. Lack of space and insufficiency of staff, however, will prevent the development of a general natural history museum. The insect collections have already been transferred to the Ministry of Agriculture and the marine invertebrates to the Sultana Hydrobiological Institute. The Zoological Service of Egypt is doing a useful work in the preservation of the natural fauna of the country both by protecting game and nesting birds and by controlling beasts of prey. Special success has attended its efforts to protect birds from the birdlimers, to preserve the breeding colonies of the cattle egrets, and to keep down the number of jackals.

AN interesting addition to the flowering plants of the British flora is announced in the November issue of the *Naturalist*. Mr. R. W. Butcher found *Tillaea aquatica* at Adel, near Leeds, in September, where it was the dominant plant growing in abundance on the drying-up mud on the margin of a pool. Dr. G. C. Druce has examined the plant, and agrees that it is probably a true native species or one brought there by purely natural means. The typical plant is known from Germany, and a sub-species also occurs in France and Italy.

THE December issue of the Journal of the Franklin Institute contains a paper by Mr. Enoch Karrer, of the Nela Research Laboratories, Cleveland, Ohio, on the shape assumed by a deformable body immersed in a moving fluid. The author's attention was directed to the subject by the behaviour of a drop of mercury just above a constriction in a vertical glass tube up which a current of gas was flowing. As the speed of the gas was increased the drop was raised above the constriction and assumed a slightly egg-shaped form with its larger end downwards. With increase of speed it elongated, keeping its larger end downwards, and finally a small drop detached itself from its upper end. From these observations the author concludes that a deformable body in a moving fluid assumes a stream-line shape. He supports his conclusion by figures of snow drifts and snow bosses from Cornish's "Waves of Sand and Snow," of egg-shaped boulders with their long axes in the direction of the wind and their big ends up-wind, and by the shapes of moths, birds, and fishes. By analogy with "geotropism"—the adjustment of organisms under gravity—the author proposes to name this new principle "rheotropism."

THE Meteorological Office of the Air Ministry has recently issued as No. 18 of the Geophysical Memoirs a memoir by Mr. W. H. Dines on observations on radiation from the sky and an attempt to determine the atmospheric constant of radiation. The measurements were made at Benson during 1920. The sky was divided into six zones of 15° width, and the radiation was taken at the altitudes corresponding to the mean altitude of the zones. The final form of instrument used was a thermopile of copper-eureka junctions designed by L. F. Richardson. The observations were made at, or a little after, sunset, and are classified under "clear sky," "overcast sky," and "very clouded sky." By suitable methods the amount of radiation received from each zone on a horizontal surface at ground-level is calculated, and the final results show that the average daily supply of heat from the atmosphere throughout the year falling on one square centimetre in the South of England on clear days is 506 gram calories. For fully clouded skies the value is about 700, with a general mean for all days of about 600. For a mean temperature of 50° F. the outward radiation from the earth is 711 gram calories, so that the net or effective radiation for a clear sky is rather more than 200 gram calories. This is 25 per cent. less than the values usually given, which, however, have been mostly obtained at much greater altitudes than Benson (186 ft. above sea-level).

THE commercial transmission of power conveyed electrically by overhead wires has made the study of lightning arresters of great importance. In places where thunderstorms are violent, such as in certain parts of South Africa or where the lines have to traverse mountainous regions, the use of efficient lightning arresters is a necessity. In this connection the papers published in the *General Electric Review* for November and December last by J. L. R. Hayden and N. A. Lougee are of value. The object of lightning arresters is to afford protection against sudden rushes of electricity at high potential in the lines due to atmospheric disturbances. To get similar electric surges in the laboratory they build up a battery of glass-plate condensers which by means of the kenotron (a two-electrode thermionic valve for rectifying currents of high voltage) can be charged by an alternating-current transformer to 30,000 volts; 200 of these condensers are used, which can be connected in parallel or in two groups of 100 in parallel or in four groups of 50 in parallel. When they are all in parallel the capacity is 1·6 microfarads, and at 30 kilovolts the energy stored is 720 joules. With the arrangements they used they got a maximum discharge of 9500 amperes at 120,000 volts, the discharge frequency being 126,000. Three types of lightning arrester were examined: (1) the horn type with resistance in series, (2) the electrolytic type, and (3) the multigap type. Their results prove that the

resistance in the horn type was very detrimental, that the electrolytic type was very efficient, but that its expense limited its use, and that the multigap type was an efficient and cheap type of lightning arrester.

MESSRS. LONGMANS AND CO. have in the press "Modern Practice in Heat Engines," by T. Petrie, which is intended to form a companion to the late W. Inchley's "Theory of Heat Engines." It deals with the subject of power from heat engines as a whole, and attempts to show how far theory may be applied to the design of modern types. The book is divided into three sections, steam boilers, steam prime movers, and internal-combustion engines, each section containing a descriptive chapter on the latest types with sectional illustrations which, in many cases, approximate to working drawings. Another book announced by the same publishers is a translation, by Dr. J. S. Thomas, of Prof. A. Smits's "The Theory of Allotropy."

MR. F. EDWARDS, 83 High Street, Marylebone, W.1, has just issued a Hand-list (No. 422) of Biographies, Autobiographies, Diaries, Journals, Correspondence, etc., of Famous Men and Women. Many men of science are represented in the catalogue.

MR. E. MARSDEN, one of the authors of "Geography for Junior Classes," of which a short notice appeared in NATURE of December 22 last, writes to point out that the phrase "lines and belts of equal heat," which the reviewer remarked "is bad anywhere," occurs also in Geikie's "Elementary Lessons in Physical Geography" and in the revised edition of Huxley's "Physiography." The use of the phrase in other books does not, however, alter the reviewer's objection to it.

IN an article entitled "Fisheries Biology" in NATURE of December 29, p. 585, it is stated that "the spur-dog and nurse-hound are viviparous." Mr. E. Ford writes to inform us that the term "nurse-hound" is applied at Plymouth to *Scyliorhinus stellaris*, which is not viviparous. We understand from the writer of our article that confusion has arisen from the fact that the name "nurse-hound" is also used by fishermen in his district to refer to *Mustelus vulgaris*, which is viviparous.

Our Astronomical Column.

THE SHOWER OF JANUARY METEORS.—A rather abundant display of these objects was observed on the night following January 3. Mr. W. F. Denning writes as follows:—At Bristol the early part of the evening was clear, and between 5.40 and 6.50 p.m. meteors appeared at the rate of thirty per hour. Clouds, wind, and sleet then interrupted watching until about 9 p.m., when the atmosphere again cleared, and the remainder of the night was splendidly favourable for observation. The shower, however, declined in numbers strikingly, for in the two or three hours preceding midnight the hourly rate of apparition was only twelve, and there was a further falling off as the night progressed. The radiant point was at $232°+53°$. Large meteors were frequent, and a number of them have been recorded at several stations. Miss A. Grace Cook witnessed the event from Stowmarket and saw a considerable number of meteors on the two nights January 2 and 3. She registered a fair proportion of large ones, and found the maximum intensity occurred in the early part of January 3. The radiant was at $231°+53°$.

SPECTRAL EVIDENCE OF A PERSISTENT AURORA.—Bulletin No. 76 (vol. 3, No. 1) of the Lowell Observatory, contains an interesting account by Mr. V. M. Slipher of his successful attempts to show that the aurora is always present in the night sky. Working on the fact that the spectrum of the aurora consists of certain emissions, of which one in the yellow-green is so intense relatively as to contain a considerable portion of the total auroral light, he finds it possible to record this line with an exposure of only a few hours, even if there be moonlight. The instrument he employs is a spectrograph with a 66 degree flint glass prism, and a Dallmeyer lens of f/1·9 ratio, the photographic plates being of the Cramer isochromatic brand. This spectrograph was usually simply pointed to the sky, but in some cases a small objective was placed in front of it. All the exposures he made showed the characteristic auroral line, thus proving the existence of auroral illumination, persistent or permanent at least over the period covered by his series of plates, which commenced in the year 1915. The two plates which accompany his paper show the auroral line clearly on both moonlight and moonless nights.

MOVEMENTS IN SPIRAL NEBULÆ.—Dr. Jeans exhibited at the November meeting of the Royal Astronomical Society some slides sent by Dr. Van Maanen, showing movements in the spirals M 101 and M 33. He demonstrated that the only tenable motions that would conserve the equiangular spiral forms were compounded of pure rotation and motion along the arms. The latter type greatly predominates in these nebulæ, and the indicated times of revolution round the nucleus are 85,000 years and 160,000 years respectively. Since only two whorls of nebulosity can be traced, implying a duration of a third of a million years, it was conjectured that the outer whorls may have become invisible, just as the puffs of steam from a locomotive soon dissipate. By the combination of observed shifts with line-of-sight velocities, a distance of 2000 parsecs was deduced for M 33. This would be fatal to the island-universe hypothesis, since it would place the object well within the confines of the galaxy. There have been fairly regular oscillations of opinion on the hypothesis, the prevailing view at the Royal Astronomical Society's meeting being hostile to it.

A BRIGHT FIREBALL.—Mr. G. E. Sutcliffe writes from Shahpur, Ahmedabad, India, that on November 22 last, at about 6 a.m., when gazing towards the Southern Cross, he saw a large fireball emerging from the horizon. The object appeared to be approaching him and to move more slowly than ordinary shooting stars. It became intensely brilliant. Its motion was directed nearly from south to north, and it passed a little to the east of his zenith. During the early part of its track the fireball was globular in shape, and it had a distinct tail like a comet.

A Notable Exhibition of Physical Apparatus.

THE Physical Society of London and the Optical Society held their twelfth exhibition of electrical, optical, and other apparatus at the Imperial College of Science on January 4 and 5. As in past years, the exhibition rooms were crowded with apparatus and visitors; the latter were so numerous that the exhibition became a continuous one instead of closing between 6 and 7 p.m. each day. The display of scientific apparatus was probably the finest ever seen in this country, and the quality and finish of the instruments left little to be desired. There were many instruments of novel design, but attention can be directed to a few only.

A quite novel exhibit was an optical sonometer by the firm of Hilger, Ltd. This is designed to record the pressure variations caused by sound-waves, and should prove invaluable to workers in acoustics. The most novel feature is the diaphragm, which is a film having a thickness of a fraction of a wave-length of light, and is silvered or gilded on one side by a cathode process. The sound-wave under examination is received by a horn, and causes the diaphragm, and ultimately a beam of light, to vibrate. An intense point image is produced, and a photographic record can be obtained on a rotating film. The vowel sounds and all kinds of acoustic disturbances may thus be analysed. In another arrangement, which is excellently adapted for demonstration purposes, a rotating band with white lines on a dark ground is illuminated by a line image from the diaphragm. By adjustment of the speed of rotation stationary wave effects are obtained.

The episcope, shown by Newton and Co., is a marked improvement on forms previously seen, and should come into more general use for the projection on screens of opaque objects. The present instrument is of beautiful design, and with its two 2000-candle-power lamps very bright pictures of opaque objects may be projected on a screen 5 metres or more away. In large teaching institutions this instrument could be put to many uses.

The Marconi Co. exhibited its new automatic alarm which responds to the wireless call of a ship in distress. In the present form of instrument the distress call must consist of three dashes, each of four seconds' duration, the dashes being separated by one-second intervals. By means of an amplifying circuit, plungers working in dash-pots are caused to respond to the four-second impulses, and after a series of three such impulses a warning signal occurs. If the impulses last for more or less than four seconds, subject to a tolerance of about half a second, the circuit necessary to operate the alarm is not completed. The demonstrations given were accompanied by artificial atmospherics and continuous wireless reception, and were remarkably successful.

Creed and Co. again showed their system of high-speed automatic printing of wireless messages, but at an increased speed of reception. Signals from Chelmsford were regularly received, the Morse code perforations in a paper strip being transposed into Roman characters by an automatic printer. The speed ranges from 50 to 200 words per minute. While the writer was present a message was received from the Marconi Co. conveying its wishes for the success of the exhibition. The receiving aerial appeared to be a very insignificant affair, and many visitors marvelled at the present efficiency of triode-valve amplifiers.

A novel weather foreteller, the design of which is due to Mr. Kitchen, was shown by Negretti and Zambra. The instrument is based on meteorological data extending over many years. The forecast for twelve hours appears in a small window in the instrument after the barometer and wind-scales have been set to correspond to the conditions existing at the time. It would be of interest to have a record over six months of "predictions" and "happenings."

Tucker's hot-wire resonator microphone was shown by H. W. Sullivan. The microphone consists of a heated wire in the neck of a resonator and is insensitive to all but the particular sound frequency which it is desired to receive. The hot wire is cooled by the oscillating air-currents at the resonant frequency, and the change in the resistance of the wire is caused to operate an amplifier.

The Cambridge and Paul Instrument Co. exhibited a novel temperature regulator, in which the current from a thermo-couple in a furnace passes through a millivoltmeter, at the end of the pointer of which is a light thermo-couple in series with a moving coil relay. When the furnace is at the temperature which it is desired to maintain, the light thermo-couple is brought, by the movement of the pointer, into close juxtaposition to a small heated body. A current is thus generated which operates the relay and indirectly controls the current in the furnace. The instrument exhibited controlled a small electric furnace at about 700° C. within about 5° C.

The Edison Swan Co. showed a 10,000-candle-power pointolite lamp of ingenious construction; many visitors remarked on the skill required to seal leads into glass for the passage of a current of 40 amperes. The firm of Ilford, Ltd., showed a new and improved colourless filter which completely cuts off ultraviolet rays. It is claimed to be much superior to the usual æsculin filter, and is known as "Q" (acetaminoquinoline). The Davison microtelescope, while not new, attracted considerable attention, and users of the microscope admired a new 25-watt mercury vapour lamp made by Chas. Baker. Shotter's integrator for water-flow meters was shown by H. Tinsley; it represents a new application of the Wheatstone bridge. Among precise measuring instruments the Campbell fundamental standard of mutual inductance (shown by R. W. Paul) must be mentioned, and also the "Talymin," by Taylor, Taylor and Hobson, which determines within small limits of error the outside diameters of small manufactured parts.

An experimental lecture on "The Johnsen-Rahbek Electrostatic Telephone and its Predecessors" was given on both days by Mr. A. A. Campbell Swinton. Another lecture on "Radium: Its Application in Peace and War" was delivered by Mr. F. Harrison Glew, and a third lecture on "The Employment of Coarse Wire Gratings in Astronomy" was given by Sir Frank W. Dyson. These lectures were attended by large audiences, and were highly appreciated.

Science in Secondary Schools

THE twenty-second annual general meeting of the Science Masters' Association, which was held last week at the Imperial College of Science, was presided over by the Master of Balliol. His address on the subject of the relationship of history and science will long be remembered by those who were fortunate enough to hear it for the genial humour and literary grace with which he defined the position and importance of these complementary branches of learning.

The association has been growing steadily in size and influence, and in recent years more than one important development in scientific education has taken its origin in the deliberations of its assemblies. Unless we are mistaken, we may expect to see, as a result of this meeting, a serious endeavour to introduce the fundamental principles of physical chemistry in the early stages of science teaching. Brig.-Gen. H. Hartley made this suggestion both in the interests of intellectual economy and of clear thinking. It was time, he said, that they tried to simplify for their pupils the memorising of the ever-growing mass of known chemical facts by showing them at the outset how these are co-ordinated; thus would pure memory work be reduced, being replaced by reasoning which was well within the powers of the students. Prof. J. C. Philip, who, in common with other speakers, strongly supported this view, emphasised the importance of introducing the physico-chemical ideas into the ordinary chemistry courses in preference to teaching physical chemistry as a separate subject at the start. It was further explained that neither expensive apparatus nor extraordinary mathematical ability on the part of the pupils is necessary in the early stages of such instruction. It is rare to find in a big gathering such unanimity of opinion that a change of this sort in traditional teaching is both desirable and possible. In all probability more will be heard of it.

During the course of the meetings, which extended over two days, there were several other discussions, of which the following general impressions were obtained:—First, as regards the teaching of dynamics; this is still, with rare exceptions, in a chaotic condition in our schools. The subject is often left in the hands of mathematical masters, and divorced from the teaching of science. In any case, the presentation of mechanics is usually far too formal, with the result that it makes little appeal to beginners.

Geography seems to be in a better way. Some attempt was made at the meeting to define, perhaps to limit, the activities of the specialist teacher of geography. But it was fairly generally agreed that he had made good, and that science has much to gain and nothing to lose by the growing importance which is being attached to the modern geographer's methods.

Major E. R. Thomas, in opening a discussion on post-certificate science for the non-specialist, spoke of the importance of emphasising the cultural value of the subject. For this class of student especially it is desirable to bring into prominence the historical, biographical, and philosophical aspects of the subject. This kind of teaching is now being widely adopted, and is already being reflected in the work of those who are specialising in science. For many years the association has done its utmost to save the youth of the country from the materialistic tendencies which may follow from the study of natural science if it is narrowly conceived and inadequately expounded.

The discussions will be fully reported in the next issue of the *School Science Review*, which Mr. G. H. J. Adlam will continue to edit. During the coming year Sir Ernest Rutherford will be the president of the association, of which Major V. S. Bryant (St. Piran's School, Maidenhead) and Major C. E. Sladden (Eton College) are the secretaries.

The annual meeting of the Association of Science Teachers was held at University College, London, on January 3 last. At a business meeting in the morning the following resolution was unanimously passed:—"That this meeting of the Association of Science Teachers deeply regrets the action of the University of Cambridge, in that, alone among British universities, it continues to exclude women from membership. The association believes that such exclusion must be prejudicial to the higher education of women in general, and especially in natural science, for the study of which Cambridge can offer exceptional advantages."

A very useful discussion on practical examinations in science, initiated by a resolution concerning general elementary science as a subject in the General School Examination of the University of London, was made more valuable by the presence of Mr. Lea, representing the University. The general sense of the meeting was in favour of the retention, or even extension, of practical tests in science as a part of the First Examination.

In the afternoon Dr. Winifred Brenchley, of the Rothamsted Experimental Station, lectured on "The Effects of Competition on Plant-life." She pointed out that competition is prevalent both above and below ground. In the soil the deficiency of any constituent of plant-food may become a limiting factor in the growth of the plant, and the elements which act most frequently in this way are nitrogen and phosphorus, and to a less extent potassium. Tests on this point are made by pot-cultures, in which the composition of the soil can be controlled. By such tests it can be shown that with scanty nourishment one plant will increase as much in dry weight as a number of plants crowded into the same amount of soil.

Above ground the limiting factor is light, leaf mosaics and other leaf arrangements being an adaptation to this condition. The effect of light is not always obvious, as crowded plants are taller than "spaced" ones, but a comparison of dry weights shows that the "spaced" plant increases 50 per cent. more than the crowded one.

Plants are adapted to live in communities on a limited amount of soil by varying root depth, *e.g.* during the drought of last summer bird's foot trefoil flourished exceedingly because it had deep roots. Cultivated plants cannot exist at all in competition with weeds. Investigations undertaken at Rothamsted have shown the extraordinary vitality of weed-seeds, and work is now proceeding on a survey of weeds of various districts. In this matter Dr. Brenchley seeks to enlist the help of schools in various parts of the country, and will be glad to send details as to the data required to anyone who can help in this way.

Problems of Animal Breeding.

An interesting series of articles on research in animal breeding appeared in the April–July issues of the *Journal of the Ministry of Agriculture*. In the first two papers the author, Prof. R. C. Punnett, traces the results of crossing red with black and polled with horned cattle, and in this way illustrates the Mendelian principles underlying all breeding methods. Mendelism not only enables the breeder to understand why red calves sometimes appear even in the most highly pedigreed Aberdeen, Angus, or Holstein cattle, but it also supplies the knowledge which can be used to prevent their ever appearing again. The factors with which breeders are concerned are rarely as simple as in the black-red case of cattle, where the possibilities form a simple alternative pair, and in both cases one of the characters is completely dominant to the other, black being dominant to red and polled to horned. A more

complex example is given by crossing black polled with red horned cattle, which in the first generation yields all black polled animals, but in the second generation a very mixed progeny arises. If the factors for the black-red and the polled-horned pairs are transmitted in the same manner, but *independently of one another*, then the second generation will consist of four classes: black-polled, black-horned, red-polled, and red-horned in the ratio of 9:3:3:1. This ratio has not been verified on a comprehensive scale for the cattle cross, but it has been worked out in all details in several cases for smaller animals. That horned-blacks and polled-reds appear in the second filial generation means that there has been a "break up" of the parental types, and the new classes arise through re-combination of the two pairs of factors in which the original parents differed.

Many of the characters of animals owe their manifestation to the presence of one or other definite factor transmitted according to a definite scheme. If these factors are not divisible under normal conditions they must be transmitted through the germ-cells as definite entities producing their full effect in each successive generation. Therefore, if these factors are relatively permanent, and follow a fixed scheme of distribution in heredity, it is obvious that the characters of living things can be brought under accurate control by the breeder. This factorial theory of heredity has been tested and proved to hold good in a large number of cases, and the problem now engaging the attention of research workers at Cambridge is to find whether it can be applied to those cases where at first sight there appears no suggestion of clear-cut alternative pairs of characters.

The last two papers of the series under notice deal with some of the experiments carried out on these lines. One of the most extensive analyses was designed to investigate the inheritance of weight in poultry. Two standard breeds were chosen; for the larger bird the Gold-pencilled Hamburgh, and for the smaller one the Silver Sebright Bantam, the latter being, roughly, three-fifths of the weight of the former. The first-cross birds were intermediate in size, but in the second generation there was a very wide variation. The majority of birds were between the weights of the original parental birds, but a few were larger than the Hamburgh, while a few were smaller than the Sebright. Nilsson-Ehle, working on wheat and oats, was the first to give an explanation of such cases, and the closeness with which the theory fitted his results left little doubt of its being a true interpretation. Essentially, his theory is that a similar effect may be brought about by more than one factor, though such factors are independently transmitted. Accordingly, if there are several similar factors, A, B, C, D, etc., which influence the weight of poultry, then a bird possessing none of these factors will be the smallest type. When it contains A, it will be rather larger; when it contains A and B, it will be larger again, and so on until the largest bird is reached which contains the full collection of the weight factors.

This theory was found to cover all the observed facts, and although it is not suggested that weight is dependent solely upon such factors, yet it seems probable that even such complicated characters can be interpreted in terms of definite factors. On the other hand, very different results were obtained in experiments on rabbits, where the large Flemish was crossed with the small Polish rabbit. In this case the F_2 generation contained no animals at all approaching the size of the original Flemish, and no explanation of this can at present be offered. Further experiments on rabbits were concerned with the inheritance of coat patterns, and the analysis of the continuous series from self-colour to almost white provided an interpretation in terms of the factorial theory.

Another interesting series of analyses dealt with the peculiar form of inheritance known as sex-linked heredity. This can be illustrated by the Hamburgh-Sebright cross used for the weight experiments. The Hamburgh was a gold-pencilled and the Sebright a silver, and the experimental work showed that silver and gold form an alternative pair, silver being a simple dominant to gold, but in the hen the transmission of the factor for silver is sex-linked. The silver hen is never pure for the silver factor; half of her eggs are "silver" and half are "gold"; moreover, she transmits the silver factors to her male-producing eggs and the gold to her female-producing eggs. A large number of birds have been bred from the mating of silver hen and gold cockerel, but there has not been one exception to the rule that the cockerels all come silver and the pullets all gold. This sex-linked type of inheritance is found in several other characters in poultry, and it may prove of economic importance, for by making use of suitable crosses the breeder of poultry for egg-production can be sure of rearing nothing but pullets through the earlier, and more costly, stages.

Further experiments dealt with the inheritance by cocks of henny feathering, while others were concerned with the characters of egg-colour and broodiness in poultry. These had to be curtailed considerably owing to war conditions, although some interesting results were obtained.

Although all these analyses may prove to be of economic value, yet it must be remembered that the "main object of the work at Cambridge is the elucidation of the principles that underlie the phenomena of heredity," and when these have been revealed the application can be left to those who will derive profit from it.

A Petrological Microscope.

WE have received for examination from Messrs. R. and J. Beck an example of their "Standard London Petrological Microscope," which they have recently designed for the use of students. It embodies some of the recommendations of a committee of the British Science Guild, which carefully considered the subject (Journal of the British Science Guild, November, 1916, pp. 28–30). The microscope, which is strongly built and stands firmly, has the following distinctive features:

The analyser is a form of the Abbe prism, devised by Mr. E. M. Nelson. It is placed immediately below the upper lens of the ocular, and slides laterally in and out of position. This arrangement, while it does not appreciably contract the field, has the advantage that it allows a quartz wedge to be inserted between the nicols in the focus of the ocular, with the result that the colour bands are sharply defined, as is also the dark band indicating the position of compensation. It is stated that in certain circumstances a faint second image of the cross wires can be seen, but it is scarcely noticeable, and causes

no inconvenience. The analyser can be rotated about the axis of the microscope, and is provided with clicks in the positions of crossed and parallel nicols. There is an arrangement by which it can be rotated alternately through small equal angles in opposite directions, from the position of crossed nicols, thus affording an accurate means of determining whether the exact position of extinction of a mineral has been arrived at.

The "directions-image," showing interference figures, is obtained, not by the insertion of a "Bertrand" lens in the tube, but by placing a "Becke" lens over the ocular. This is decidedly preferable as it enables the optical effects of a small crystal or twin lamella to be isolated by first placing a diaphragm, with a hole of suitable dimensions, in the focus of the ocular, so as to hide everything except the object to be studied, and then putting the Becke lens into position. The diaphragm is so constructed that it allows of the insertion of a gypsum plate or quartz wedge immediately above it.

These arrangements render it unnecessary to cut into the tube of the microscope to allow of the introduction of the analyser and the Bertrand lens. This means less labour in construction, and therefore less cost.

It may be added that the upper lens of the ocular is adjustable, so as to admit of its being exactly focussed on the quartz wedge, the cross wires, or the perforation in the diaphragm, and there is also an adjustment of the Becke lens for the purpose of focussing the interference figures.

The polariser is conveniently placed in a swing-out below the stage. It has a slot immediately below it for the insertion of a diaphragm with a small circular or linear aperture for comparing the refractive indices of adjoining minerals by the Becke method, and other purposes.

When it is required to insert the condenser it is slid up into a cylindrical fitting in the stage. This is not very convenient, but we are informed that the firm is arranging to substitute a swing-out attachment, which it is believed will prove in every way satisfactory.

An interesting feature is the Sloan objective changer, which takes only two or three seconds to operate. Each objective is attached to a collar by means of two screws. When these are once correctly adjusted, the objective will always be found to be correctly centred immediately on insertion.

Among the accessories is a quartz wedge cemented to a gypsum plate, and graduated in intervals of fifty micromillimetres of relative retardation. This should render unnecessary the quarter-wave mica and Klein's plate, which are, however, still retained in the list of accessories.

It may be suggested that the fine adjustment should be provided with a milled head graduated to five microns on its circumference, even if it were only approximately accurate.

Archæology in Mexico.

AT a meeting of the Royal Anthropological Institute on November 22 Mrs. Zelia Nuttall gave an account of recent archæological investigations in Mexico. As an introduction to her report Mrs. Nuttall referred briefly to the fact that after a period of quiescence of some centuries the great volcano Popocatapetl had again become active in 1920, and that its activity still continued.

During the last decade evidence that great volcanic disturbances had taken place at long intervals has been forthcoming. Two distinct types of figurines have been found in conditions which indicate that the topography of the valley has been changed and its inhabitants destroyed by great catastrophes antedating the arrival of the Nahuas or Aztecs.

Of these figurines the first, provisionally distinguished as the sub-gravel type, was brought to Mrs. Nuttall's notice in 1909, when specimens were offered for sale by Indians, and she herself discovered an example *in situ* under a gravel bed at Atzacapotzalco. They were delicately fashioned of fine clay, with slender bodies, long faces, smooth-hanging hair, some wearing chaplets. All presented a worn and polished surface. In the Valley of Mexico the gravel beds extend under the lava flow at the base of the extinct volcano Ajusco.

Under the lava bed, to which Dr. Tempest Anderson assigns an age of at least 20,000 years, Mrs. Nuttall in 1908, and afterwards Señor Gamio, head of the Department of Archæology of Mexico, have discovered a second type of figurine, to which the name "sub-lava type" has been given. This type is characterised by turbans and caps, evidently of fine stuffs or fur, and decorated with circular ornaments of stone or shell. They indicate that the southern part of the valley was inhabited by a race totally distinct from that of the "sub-gravel type" and the Aztec. The distribution of the clay figurines is now under investigation. They have been traced as far as Guatemala.

Mrs. Nuttall also described the results of recent excavations at Teotihuacan, during which a small pyramid was opened up and reconstructed by Señor Gamio. A tunnel pierced at the height of 35 ft. to the centre of the pyramid revealed that it had been formed of mud filled with innumerable fragments of pottery vessels which had prevented the mud from cracking when it baked in the sun. A remarkable discovery was that of the remains of the ancient pyramid temple with a wonderful sculptured frieze which had been partly destroyed and then concealed by another terraced pyramid temple built in front. The sculptured serpents' heads and the masks of the water-god Tlaloc are of a form hitherto unknown. Associated with them are sculptured shells, principally the conch shell and the pecten or pearl shell. Not only is it remarkable that sea-shells should be represented in sculpture in the heart of the continent, but the association of the water-god with the ocean is entirely new.

In the discussion which followed Mrs. Nuttall's paper, Mr. Maudslay expressed the hope that it might be possible before long, by the elaboration of a system of stratification, to date Mexican antiquities. As Mexico appeared to have been untouched by outside influence, the study of its antiquities afforded evidence of the highest value for the study of the development of the human mind acting by itself. Mr. T. A. Joyce emphasised the importance of the evidence relating to the figurines, and pointed out that the British Museum had acquired a figurine of similar technique from Ecuador. Prof. Elliot Smith expressed the opinion that, contrary to what had been stated by Mr. Maudslay, Mexican antiquities showed clear evidence of influence from outside, and in particular from Asia. Mrs. Nuttall's work showed that this culture must have crossed the Pacific.

The Treasury Grant to Universities.

WE have already referred on several occasions to the proposed reduction, from 1,500,000*l.* to 1,200,000*l.*, in the Treasury grant-in-aid of university education for the coming financial year 1922–23. A memorandum, in which the dangers of reducing the grants and the rightful claims of the universities are ably stated, signed by the Vice-Chancellors of the Universities of Birmingham, Durham, Leeds, Liverpool, Manchester, and Sheffield, has been forwarded to the Prime Minister. The document has also received the approbation of the Vice-Chancellors of the Universities of Oxford, Cambridge London, Bristol, Glasgow, Aberdeen, and Wales. As we have repeatedly pointed out, the universities are the chief centres of research; they advance science and, to regard the matter from the purely commercial side, they have unquestionably added millions to the national wealth by the way in which they have enriched industry and commerce. In return for their great services, and in order to continue to be able to give such service, they are asking the Government to assist in maintaining their relatively modest financial resources. Encouraged by the hope that funds raised locally would be met by a corresponding increase in Treasury grants, great efforts have been made and every form of self-help employed; severe economy has been practised in structural expenditure and in the maintenance and equipment of laboratories; students' fees have been increased so that one-third of the total income of the universities of the North is derived from this source; private benefactors have given 1,175,000*l.* in response to urgent appeals; and local authorities have increased their grants to these universities from 74,268*l.* in 1913–14 to 135,868*l.*

In spite of this effort and the proportion of the Treasury grant allocated to the universities of the North of England, heavy losses were sustained in the working of the last academic year. It is therefore considered that with a curtailment of the existing grant the efficiency of the universities will be seriously impaired. In other countries, with which Britain must come into competition, efforts are being made to increase the resources of the universities. It is only necessary in this connection to recall the case of McGill University of Montreal, which has recently received sums amounting to seven million dollars in gifts from private benefactors and subsidies from public funds. The universities are admittedly of prime national importance, and when their resources, exploited to the uttermost, are insufficient for the maintenance of efficiency and vigour, it becomes a national duty to provide the necessary additional funds.

The Royal Academy Winter Exhibition.

THE exhibition which opened this week of works by recently deceased members of the Royal Academy affords an opportunity of comparing the pictures which have been exhibited at different dates during the past fifty years with those of the present time as shown year by year at the summer exhibitions. Even a rapid tour round the galleries shows that, so far as landscapes and Nature studies are concerned, the past can well bear comparison with the present, the number of unsatisfactory representations of Nature in the present exhibition being remarkably few. This does not prove that such pictures were not exhibited fifty years ago; it may indicate only that the Selection Committee in making choice has avoided pictures of that type. It may, on the other hand, indicate that "recently deceased members" were less addicted to post-impressionism and similar phases of art than those still living.

Thirty-six artists are represented in the exhibition. Of those who excelled in landscapes Sir Ernest Waterlow must be mentioned. He is represented by eighteen works of almost uniform excellence. Alfred Parsons's landscapes are equally pleasing, particularly No. 233, "River Scene," first exhibited in 1878. His garden pictures are not quite so successful, the flowers not presenting in all cases an entirely natural appearance. Napier Hemy, whose sea paintings are so well known, is represented by several of these works, and also by views of the Thames in London, of which No. 80, "The Riverside, Chelsea" (1873), derives an added historical interest as showing a wooden bridge over the Thames in the foreground, the familiar square tower of Chelsea old parish church being seen behind. Much more ancient history is shown in "The Catapult" (No. 208), a stout wooden apparatus manipulated by Roman soldiers in the siege of a walled city. The construction looks strangely modern.

Peter Graham's works show much more variety than was to be found in his recent paintings. One of the earliest shown, "A Spate in the Highlands" (No. 105), exhibited in 1866, is typical of his modern work with hill-mist in a Scotch glen, but without cattle. Then in 1873 came a Highland farm scene, and in 1896 and 1898 two really excellent pictures of sea and rocks (Nos. 191 and 216). It is a great pity that a subject in which the artist showed such skill should have been entirely discarded later in favour of the mountain scenes, successful as these were. It would not be fitting to close this note without favourable mention of Briton Riviere's numerous scenes from animal life, some of which are very striking.

J. S. D.

Botany of the Argentine Republic.

THE Anales (vol. 29, 1917) of the Museo Nacional de Historia Natural de Buenos Aires, recently received, a bulky volume of 700 pages, is devoted to the botany of the Argentine Republic. The earlier portion of the book contains the first part of a catalogue of the flowering plants, with the preparation of which Messrs. Hauman and Vanderveken have been occupied since the foundation of the botanical section of the museum in 1914. The catalogue consists of a list of all the species recorded for the area, under their families, which are arranged according to Engler's system. The entries in each family have been revised by the latest monograph dealing with the family in question. Under each species references are given to the publications on the authority of which the species is included. A systematic enumeration of the results of botanical explorations in this large area of temperate and sub-tropical South America has been much needed, and it is to be hoped that the authors will carry it to completion. A communication by Mr. Hauman on the orchids of the Argentine gives some indication of the work which remains to be done.

Two main groups are represented, a sub-Antarctic (Patagonian-Andine) and a sub-tropical, the latter being the more important. The present work has increased by 50 per cent. the number of genera and species belonging to the sub-tropical group. Mr. Hauman also supplies a number of floristic notes, which conclude the series of memoirs he has already published on the Monocotyledons of the Argentine, in which he has added some seventy species to the flora, about one-third of which are new. The volume concludes with a revision by Mr. Carlos Spegazzini of the Argentine Laboulbeniales, that remarkable group of minute fungi which live parasitically on insects. The enumeration includes 213 species, each of which is carefully figured; a large proportion are described for the first time. The volume is a very important contribution to our knowledge of the botany of temperate South America.

University and Educational Intelligence.

DR. A. SMITH WOODWARD will give a lecture on fossil man, with special reference to the Rhodesian skull, on Tuesday, January 24, at 5.30 p.m. at University College, London. Tickets for the lecture, at 5*s*. and 2*s*. 6*d*., can be obtained from the Secretary of the college. The proceeds will be devoted to the St. Christopher's Working Boys' Club in Fitzroy Square, which is largely worked by students and members of the staff of University College. The chair will be taken at the lecture by the Right Hon. the Earl of Plymouth, who is president of the club.

THE second term at University College, London, begins on Tuesday next, January 17. The following are some of the public lectures to be given during the term:—"Industrial Unrest," by Mr. B. Seebohm Rowntree; "The Bridges of London," by Mr. A. T. Walmisley; "The Preservation of Ancient Buildings," by Mr. A. R. Powys; "The Evolution of Man" (four lectures), by Prof. G. Elliot Smith; "The University of London: Its History, Present Resources, and Future Possibilities," by the provost, Sir Gregory Foster; and two lectures by Sir George Aston on "Some Principles of Amphibious Warfare" and "War History and its Application." A copy of the full programme may be obtained by sending a stamped addressed envelope to the Secretary, University College, London, W.C.1.

THE annual general meeting of the Incorporated Association of Head Masters was opened on January 4 at the Guildhall, and the new president, Mr. C. M. Stuart, delivered his inaugural address. Mr. Stuart stated that the two most revolutionary changes in education—the introduction of the schemes for 25 per cent. of free scholars and advanced courses—were instituted without consultation with secondary school representatives. In consequence, the original schemes had already required several modifications. The whole scholarship system needed reform based upon the study of the capacities of boys. In making awards it was of no use to go below the first 10 per cent., for this meant rewarding mediocrity, and it was by no means certain that the best from among the mediocrity were selected. The following resolution was carried unanimously by the meeting:—"That this meeting, while recognising the need for economy in every department, is of opinion that the recently awakened public interest in education demands that no hindrance of any kind shall be placed in the way of educational progress."

Calendar of Industrial Pioneers.

January 13, 1890. Daniel Adamson died.—A pioneer in the use of Bessemer steel for boilers, in the application of hydraulic power for riveting, and in the use of high-pressure steam, Adamson in 1861 built one of the earliest triple expansion engines. He became the head of the Penistone Ironworks, served as president of the Iron and Steel Institute, and was one of the chief promoters of the Manchester Ship Canal.

January 14, 1908. John Macfarlane Gray died.—When manager of a works at Liverpool Gray in 1866 constructed for the s.s. *Great Eastern* the first successful steam steering engine, thus enabling one man to do what had previously required as many as one hundred. He was well known for his writings on thermo-dynamics and his advocacy of the application of scientific principles to engine construction.

January 14, 1830. Johan Georg Repsold died.—The founder of the famous firm of instrument makers, Repsold was born in 1771, and was long connected with the Hamburg Fire Brigade. He introduced improvements in meridian circles and supplied many instruments to the large observatories.

January 15, 1900. Thomas Egleston died.—After graduating at Yale, Egleston studied for some years at the Ecole des Mines in Paris, and in 1863 initiated the plan for the School of Mines of Columbia University, New York, where he held the chair of mineralogy and metallurgy for thirty-three years.

January 17, 1909. Francis Elgar died.—Trained in Portsmouth Dockyard, Elgar became one of the first fellows of the Royal School of Naval Architecture and Marine Engineering at South Kensington. He was assistant to Reed, Adviser to the Japanese Government, John Elder professor of naval architecture at Glasgow, Director of Dockyards, and head of the Fairfield Shipbuilding Company.

January 17, 1833. Friedrich König died.—At the age of thirty-two, in 1806 König removed from Leipzig to London, and in 1811 with Andreas Friedrich Bauer (1783–1860) patented the printing machine in which the paper was pressed against the type by a revolving cylinder. On November 28, 1814, the *Times* was first printed on one of König's machines driven by a steam engine, "a memorable day in the annals of typography."

January 18, 1861. John Heathcoat died.—A journeyman frame-smith, Heathcoat at Loughborough in 1808–9 brought out his lace-making machines. The first square yard of plain net sold for 5*l*.; the price in 1890 was 5*d*., while the annual value of the trade had grown to 4,000,000*l*. Heathcoat's factory at Loughborough was destroyed by the Luddites in 1816 and he removed to Tiverton.

January 18, 1865. James Beaumont Neilson died.—While in charge of the Glasgow Gasworks, where he introduced clay retorts and the use of sulphate of iron as a purifier, Neilson experimented on the air-supply for blast-furnaces, and in 1828 patented the "hot blast," which enormously increased the production of iron and made available the black band ironstone discovered by David Mushet. It has been said Neilson did for iron manufacture what Arkwright did for the cotton industry.

January 18, 1873. Pierre Charles François, Baron Dupin, died.—A student of the Ecole Polytechnique, Dupin first gained distinction by his papers on naval architecture and engineering. He made a profound study of the industries of Great Britain and was one of the first in France to raise statistics to the rank of a science.

E. C. S.

Societies and Academies.

LONDON.

Geological Society, December 21, 1921.—Mr. R. D. Oldham, president, in the chair.—H. B. **Milner**: The nature and origin of the Pliocene deposits of the County of Cornwall and their bearing on the Pliocene geography of the south-west of England. Tertiary deposits of Cornwall at St. Agnes, St. Erth, Lelant Downs, Polcrebo, and St. Keverne have been provisionally assigned to the Pliocene period; except those of St. Erth, all are unfossiliferous. The average composition of the St. Agnes, St. Erth, and St. Keverne deposits is substantially the same. On this basis correlation of the deposits is effected by (*a*) the frequency of occurrence of individual species, (*b*) their persistence or distribution, and (*c*) the constancy of crystallographical, physical, and optical properties of grains of the same mineral, wherever met. The source of the material is essentially local. The gradual "swamping" of sediment-bearing rivers by the advancing Pliocene sea from the south-west is correlated with certain physical features apparent, especially the "400-ft. plateau."—L. **Owen**: The phosphate deposit of Ocean Island. Ocean Island, in the Western Pacific Ocean, consists of a mass of terraced and dolomitised coral-limestone which rises to a height of 300 ft. above low water, spring tide. Its surface is almost completely covered by a capping of calcium phosphate of exceptional purity which can be divided into three varieties: (*a*) Amorphous calcium phosphate, formed of the insoluble residue of the original guano; (*b*) detrital coral-limestone, converted into calcium phosphate by solutions leached from the guano; and (*c*) phosphatised coral *in situ*. The percentage of tricalcium phosphate at any point varies in a remarkably regular manner, according to the position of the point on the island, suggesting that (*a*) the original guano was deposited on the coral base during a slow negative movement of the strand-line, and (*b*) subsequent to the formation of phosphate the island was tilted at about a third of a degree south-south-eastwards.

EDINBURGH.

Royal Society, December 5, 1921.—Prof. J. W. Gregory, vice-president, in the chair.—Prof. **Jehu**: Observations on the geology of Iona. The Archæan complex of the western and greater part of Iona consists mainly of orthogneisses of dominant acid and hornblendic types, although pyroxene-hornblende gneiss and garnetiferous pyroxene granulites also occur. Paragneisses of various kinds are found at isolated localities as lenticular masses in the orthogneisses. On the south coast the forsterite-tremolite marble (Iona marble) is associated with hornfelsed green rocks, some of which are altered sediments and some altered igneous rocks. The paragneisses are younger than, and unconformable to, the orthogneisses, and represent remnants of pre-Torridonian rocks which became infolded with the orthogneisses. A massive white pegmatite forms a prominent feature in the landscape from the marble quarry on the south coast to near the centre of the island. A belt of Torridonian beds lying unconformably on the Archæan forms the eastern margin of the island, and consists of a lower group of epidotic conglomerates and grits and an upper group of finer grits, slates, shales, and banded flags. The Torridonian series of Iona may be correlated with the lower parts of the Diabaig group of that series in Skye and other districts. In post-Torridonian time the Archæan and Torridonian rocks have been subjected to isoclinal folding, the Archæan series being dragged more or less into approximate parallelism with the Torridonian. Along the line of junction there has been considerable crushing, but no actual thrust. The Torridonian rocks show dynamic metamorphism, and the later intrusion of the Ross of Mull granite has resulted in a later thermal metamorphism. This granite forms three small islets close to the south-east shore, and probably underlies the southern half of Iona. A series of genetically connected minor intrusions occur, and, with the granite, belong probably to the Caledonian phase of igneous activity.—H. M. **Cadell**: The geology of the Blackness district. Recent borings for oil-shale and coal in the Blackness district south of the Firth of Forth have not disclosed much mineral wealth, but have provided a complete vertical section of the Oil-Shale series in that region, indicating a notable attenuation of the whole shale section towards the north and west. To the west of Blackness no workable oil-shale was found above the Burdiehouse Limestone, although the positions of the seams were recognisable. The borings were continued westward up to the Bo'ness coal-seams of the Carboniferous Limestone series through ground that had never been previously explored. Six distinct beds of limestone had been found varying much in thickness from place to place. The No. 5 limestone measuring from the top downwards appeared from its fauna to be the equivalent of the Blackhall Limestone of the West of Scotland. The old volcano of Binns Hill to the south of Blackness belonged to the volcanic horizon situated near the top of the oil-shale section between the Two Feet Coal and the overlying Raeburn Shale seam. There had been much boring and mining for shale under the east end of the hill, and the evidence showed that within a few hundred yards of the thick ash on the hill there was no ash under the Raeburn Shale where it was to be expected. Binns Hill had been a very small volcano, one of a group that emitted showers of ash after the formation of the Houston and Two Feet Coal seams over a district extending southward about seven miles. Under the whole district and below the Burdiehouse Limestone there was a large intrusive basalt sill, and Binns Hill and other small local ash-necks seem to have acted as geological safety-valves by which imprisoned gases escaped and blew up part of the fluid eruptive rock in the form of fine dust and ashes.

PARIS.

Academy of Sciences, December 27, 1921.—M. Georges Lemoine in the chair.—The president announced the death of Prof. Schwarz, correspondant for the section of geometry.—E. **Borel**: Quasi-analytical functions with real variables.—W. **Kilian**: A problem of the tectonic of the sub-Alpine chains of Dauphiné.—C. E. **Guillaume**: Recent fundamental determinations and verifications of the standard metres. Slight elongations in the lengths of the working standard metres of the International Bureau have been proved. The cause of the change is not clear, but is possibly due to the effects of cleaning. Recent determinations of the coefficients of expansion of the bars have proved a small error in the opposite direction, and at the present time these errors compensate each other at about 15° C.—M. **Gevrey**: The determination of the integrals of partial differential equations, order $2p$, and m variables, admitting a multiple family of characteristics of order p.—G. **Bertrand**: Fredholm's equation and static masses of the first kind.—M. **d'Azambuja**: A mode of graphical representation of the filaments of the upper layer of the solar chromosphere.—J. **Villey**: The adiabatic liquefaction of fluids.

In a recent communication M. Bruhat has deduced from thermodynamical reasoning that the heat of vaporisation of a liquid at the absolute zero tends to a limiting value, not zero, and also that an adiabatic expansion sufficiently extended should always result in liquefaction. These conclusions have been objected to by M. Ariès. The author now shows that on the basis of the kinetic theory M. Bruhat's results are probable.—L. **de Broglie**: The theory of the absorption of the X-rays by matter and the principle of correspondence.—A. **Dauvillier**: Contribution to the study of the structure of the elements of intermediate atomic weight.—E. **Carvallo**: The problem of relativity in dielectrics.—R. **Boulouch**: The problem of achromatism.—H. **Pélabon**: The constitution of selenium. Different specimens of grey selenium are regarded as mixtures in variable proportions of two modifications, α and β, the α modification having a high resistance, the β a low resistance. The change in the specific resistance with temperature shows that the α changes into the β modification with absorption of heat. It is the α-selenium which is sensitive to light.—C. **Staehling**: The radio-activity of the uranium oxides. The changes in the radio-activity of the green oxides of uranium are attributed to the slow absorption of moisture; the black, strongly ignited oxide has a constant radio-activity, and is not hydrated on standing.—P. **Woog**: Relations between molecular properties and the capacity of fixing iodine of certain hydrocarbons.—M. **Samec** and V. **Ssajevič**: The composition of agar.—A. **Schoep**: Kasolite, a new radio-active mineral. The mineral was found at Kasolo, Belgian Congo, and occurs along with curite and chalcolite. It contains lead and uranium, and analysis gives the composition as

$$3PbO \cdot 3UO_3 \cdot 3SiO_2 \cdot 4H_2O.$$

—H. **Hubert**: New researches on the storm squalls in western Africa.—A. **Petit**: The cytology of two bacteria.—L. **Daniel**: New researches on grafts of Helianthus. An account of further experiments of grafting sunflowers on Jerusalem artichokes, with special reference to the weights of the tubers.—L. **Emberger**: Contribution to the cytological study of the sporangium in ferns.—M. **Boel**: The automatic adaptation of the angle of attack of flight in living insects. Study on the mechanism of natural flight.—M. **Nicloux** and G. **Welter**: The gravimetric quantitative micro-analysis of urea. Application to the estimation of urea in 1 c.c. of blood. The urea is precipitated as xanthylurea, and weighed on a Kuhlmann balance to 0·001 milligram.—E. **Aubel**: The attack of glucose and levulose by the pyocyanic bacillus. Glucose gave formic and acetic acids, with some ethyl alcohol. Levulose gave the same products, together with lactic acid.—E. **Chatton** and A. **Lwoff**: A new family of Acinetians, Sphenophryidæ, adapted to the branchia of the acephalous molluscs.—P. **Courmont**, A. **Rochaix**, and F. **Laupin**: The rhythm of the disappearance of ammonia in the course of the purification of sewage by activated sludge.—A. **Lumière**: The mechanism of the accidents caused by the injection of the serum of epileptics.—L. **Blum**: The antiphlogistic action of calcium salts.

Diary of Societies.

THURSDAY, JANUARY 12.

ROYAL AERONAUTICAL SOCIETY (Juvenile Lecture) (at Royal Society of Arts), at 3.—Major D. C. H. Hume: Boats that Fly.

LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5.—J. E. Campbell: Einstein's Theory of Gravitation as an Hypothesis in Differential Geometry (II).—Miss G. D. Sadd: Rational Plane Curves.—Fritz Lettenmeyer: Neuer Beweis des allgemeinen Kroneckerschen Approximationssatzes.—T. Carleman: A Theorem Concerning Fourier's Series.—T. Stuart: Parametric Solutions of Certain Diophantine Equations.—W. P. Milne: Apolarity and the Weddle Surface.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—Exhibition of Cinematograph Films.—P. Torchio, with explanatory notes by Dr. C. C. Garrard: Investigations and Tests on High-tension Switchgear.—F. Gill: Telephone Inventors of To-day.—F. Gill: The Audion.—F. Gill: Electricity in the Home.

OIL AND COLOUR CHEMISTS' ASSOCIATION (at Food Reform Club, 2 Furnival Street, E.C.), at 7.30.—A. H. Keable: Super Centrifugal Force and its Application to the Clarification of Varnish and Dehydration of Oil.

OPTICAL SOCIETY (at Imperial College of Science and Technology), at 7.30.—Dr. C. J. Peddle: The Manufacture of Optical Glass.—Dr. J. W. French: The Barr and Stroud 100 ft. Self-contained Base Rangefinder.—T. Smith: The Optical Three Apertures Problem.

INSTITUTE OF METALS (London Section) (at Sir John Cass Technical Institute), at 8—Col. N. Belaiew: The Inner Structure of the Crystalline Grain.

HARVEIAN SOCIETY (Annual General Meeting) (at 11 Chandos Street, W.1), at 8.15.—Dr. G. de Bec Turtle: Some Points on Spasm in the Alimentary Tract (Presidential Address).

ROYAL SOCIETY OF MEDICINE (Neurology Section), at 8.30.—Sir Frederick Mott and Dr. Uno: Changes in the Brain in Cases of Surgical Shock.

SOCIETY OF ANTIQUARIES, at 8.30.

FRIDAY, JANUARY 13.

ROYAL ASTRONOMICAL SOCIETY, at 5.—J. S. Paraskévopoulos: Jupiter in 1915 and 1916: Rotation Period in Different Latitudes, from Observations at the National Observatory, Athens.—Prof. G. Forbes: Solar Motion from 1922 Radial Velocities.—Major W. J. S. Lockyer: The Use of a Graduated Wedge in Stellar Classification and Parallax Work.

ROYAL SOCIETY OF MEDICINE (Clinical Section), at 5.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—E. C. West: Artificial Ice.

ROYAL SOCIETY OF MEDICINE (Ophthalmology Section), at 8.30.—M. L. Hepburn: Experience Gained from 150 Trephine Operations for Glaucoma.—H. Neame: Epibulbar Leucoma with Intraocular Involvement.

MONDAY, JANUARY 16

ROYAL GEOGRAPHICAL SOCIETY (at Lowther Lodge, Kensington Gore), at 5.—O. J. S. Crawford: The Archæology of the Ordnance Survey Maps.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Hunterian Lecture.

SOCIETY OF CHEMICAL INDUSTRY (London Section) (at Chemical Society), at 8.—E. H. Richards and G. C. Sawyer: Further Experiments with Activated Sludge.

ARISTOTELIAN SOCIETY (at University of London Club, 21 Gower Street), at 8.—H. J. Paton: Plato's Theory of εἰκασία.

TUESDAY, JANUARY 17.

ROYAL HORTICULTURAL SOCIETY, at 1.
ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. F. H. A. Marshall: Physiology as Applied to Agriculture (1).
EUGENICS EDUCATION SOCIETY (at Royal Society), at 5.—Sir Frederick Mott: The Neuroses and Psychoses in Relation to Conscription and Eugenics.
ROYAL SOCIETY OF MEDICINE (General Meeting), at 5.
ROYAL STATISTICAL SOCIETY (at Royal Society of Arts), at 5.15.—H. W. Macrosty: Some Current Financial Problems.
ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—H. V. Lawley: Automatic Methods of Kinematograph Film Processing.
ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Dr. H. S. Stannus: Arts and Crafts from Nyassaland.
ROYAL SOCIETY OF MEDICINE (Pathology Section), at 8.30.—Sir G. Lenthal Cheatle: Multicentric Origin in a Case of Rodent Ulcer of the Trunk.—J. B. Buxton: Grass-disease and Botulismus.—Dr. A. B. Rosher and Dr. H. A. Fielden: Agglutinins for Bacilli of the Salmonella Group in Sera obtained from the General Population.—Dr. W. W. C. Topley: The Effect of Dispersal during the Early Stages of a Mouse-epidemic.

WEDNESDAY, JANUARY 18.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Hunterian Lecture.
ROYAL SOCIETY OF MEDICINE (History of Medicine Section), at 5.—Dr. F. P. Wilson: The Plague in Shakespeare's London.
GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Prof. A. C. Seward and R. E. Holtum: Jurassic Plants from Ceylon.—F. S. Wallis: The Carboniferous Limestone (Avonian) of Broadfield Down (Somerset).
ROYAL METEOROLOGICAL SOCIETY, at 7.30.—Annual General Meeting.—R. H. Hooker: The Weather and the Crops in Eastern England, 1885-1921.
ENTOMOLOGICAL SOCIETY OF LONDON, at 8.—Annual Meeting.
ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 8.—W. Stoneman: Faces, Famous, Fair, and Funny.
ROYAL MICROSCOPICAL SOCIETY, at 8.—Prof. J. Eyre: Microscopy and Oyster Culture (Presidential Address).
ROYAL SOCIETY OF ARTS, at 8.—J. S. Huxley: Recent Advances in the Determination of Sex in Animals.
SOCIETY FOR CONSTRUCTIVE BIRTH CONTROL AND RACIAL PROGRESS (at Essex Hall, Essex Street), at 8.30.—Earl Russell and others: Discussion: Divorce and Birth Control.

THURSDAY, JANUARY 19.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—S. Gordon: Mountain Birds of Scotland.
ROYAL SOCIETY, at 4.30.—*Probable Papers*.—Prof. L. Hill, H. M. Vernon, and D. H. Ash: The Kata-Thermometer as a Measure of Ventilation.—Lt.-Col. C. B. Heald and Major W. S. Tucker: Recoil Curves as Shown by the Hot Wire Microphone.—E. W. A. Walker: Studies in Bacterial Variability: The Occurrence and Development of Dys-agglutinable, Eu-agglutinable, and Hyper-agglutinable Forms of Certain Bacteria.—Marjory Stephenson and Margaret Whetham: Studies in the Fat Metabolism of the Timothy Grass Bacillus.—J. A. Gardner and F. W. Fox: The Origin and Destiny of Cholesterol in the Animal Organism. Part 12: The Excretion of Sterols in Man.—Dr. S. J. Lewis: The Ultra-violet Absorption Spectra and the Optical Rotation of the Proteins of the Blood Sera.
LINNEAN SOCIETY OF LONDON, at 5.—Dr. E. Marion Delf: Studies in *Macrocystis pyrifera*, the Giant Alga of the Southern Temperate Zone.—J. L. C. Musters: The Flora of Jan Mayen Island.
ROYAL SOCIETY OF MEDICINE (Dermatology Section), at 5.
INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.—J. F. Allan: A Typical Example of Magmatic Injection.—W. E. Whitehead: Steep Sights in Underground Surveys.
ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.30.—Brig.-Gen. R. K. Bagnall-Wild: Aeroplane Installation.
INSTITUTION OF ELECTRICAL ENGINEERS (Joint Meeting with Institution of Heating and Ventilating Engineers), at 6.—Discussion: The Utilisation of Waste Heat from Electrical Generating Stations, with the following Introductory Papers: C. I. Haden: Utilisation of Exhaust Steam from Electric Generating Stations, and Coal Economy.—F. H. Whysall: The Utilisation of Waste Heat from Electrical Generating Stations.
CHEMICAL SOCIETY, at 8.—Prof. A. Smithells: Models of the Lewis-Langmuir Atom, with Explanations.

FRIDAY, JANUARY 20.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Hunterian Lecture.
ROYAL SOCIETY OF MEDICINE (Otology Section), at 5.—A. Tweedie: Short Account of the Research Work being conducted in Utrecht on the Saccular, Utricular, and Allied Reflexes (continued).
INSTITUTION OF MECHANICAL ENGINEERS, at 6.—H. S. Denny and N. V. S. Knibbs: Some Observations on a Producer-gas Power Plant.
ROYAL SOCIETY OF MEDICINE (Electro-therapeutics Section), at 8.30.—Dr. Zimmern, Dr. Agnes Savill, Dr. Sloan-Chesser, Dr. C. A. Robinson, Dr. W. J. Turrell, and others: Discussion: Electro-therapy in Gynæcology.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir James Dewar: Soap Films and Molecular Forces.

SATURDAY, JANUARY 21.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. C. Macpherson: The Evolution of Organ Music (1).

PUBLIC LECTURES.

(*A number in brackets indicates the number of a lecture in a series.*)

THURSDAY, JANUARY 12.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, at 6.—Dr. W. K. Sibley: Electrical Treatments—Diathermy, etc. (Chesterfield Lecture).

THURSDAY, JANUARY 19.

KING'S COLLEGE, at 5.30.—Dr. O. Faber: Reinforced Concrete (1).
ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, at 6.—Dr. W. Griffith: Diseases of the Skin Appendages (Chesterfield Lecture).

FRIDAY, JANUARY 20.

METEOROLOGICAL OFFICE, SOUTH KENSINGTON, at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (1).
KING'S COLLEGE, at 5.—Prof. R. Robinson: Orientation and Conjugation in Organic Chemistry from the Standpoint of the Theories of Partial Valency and of Latent Polarity of Atoms (1).
KING'S COLLEGE, at 5.30.—Rev. Dr. F. A. P. Aveling: Matter, Mind, and Man.

SATURDAY, JANUARY 21.

UNIVERSITY COLLEGE, at 10.30 a.m.—A. Chaston Chapman: Yeast: What it is, and what it does (Lecture for Teachers).
LONDON DAY TRAINING COLLEGE, at 11 a.m.—Prof. J. Adams: The School Class (1).

British Scientific Instruments.

THE exhibition of British scientific instruments held under the auspices of the Physical Society and the Optical Society at the Imperial College of Science and Technology, of which a description was given in our columns last week, is a timely reminder of the importance of scientific instruments in the national economy. Modern civilisation is based, and must be increasingly dependent, on the extension of scientific knowledge and its applications to industry; and in these developments scientific instruments are an essential and predominant factor.

Of the part played by scientific instruments in the advancement of scientific knowledge there is no need to speak. The laboratories of the universities and kindred institutions where scientific research is prosecuted would be disabled were they without scientific instruments of the highest trustworthiness and precision. The variety and extent of the industrial purposes served by scientific instruments are so great that there is probably no important industry in the country which is not dependent on scientific instruments of one kind or another for the performance of its productive functions. Moreover, the field of application of scientific instruments is constantly widening; the uses of the microscope in the textile and steel industries, of the polarimeter in the sugar and essential oil industries, of the pyrometer in the metallurgical industry, and of X-rays in the iron and steel industries, are but a few of the many examples that could be cited to illustrate the invasion of scientific instruments into fields of industry in which they were at one time unknown. That the industries gain in sureness and accuracy and in a deeper and wider knowledge of the fundamental scientific principles involved is obvious. And the process continues and must continue. To-morrow new instruments will be devised and new uses found for old instruments.

Moreover, as was stated in the leading article published in NATURE of February 10, 1921, the scientific instrument industry, springing directly from the loins of science, and progressing as scientific knowledge widens, is one of the most highly skilled industries we have. Its expansion means a definite increase in the numbers of academic and technical scientific workers and of the most highly skilled artisans; and the national wealth, in any comprehensive conception of the term, must be enlarged by the increase of the numbers of such educated and skilled classes.

For these and other reasons a flourishing and efficient scientific instrument industry is vital to the nation, whether in peace or war. And, although it is obvious that the users of scientific instruments, whether in the industrial or academic domain, must not be prejudiced or hampered by being unable to obtain the best instruments, from whatever source, it would be a disaster of the first magnitude if British scientific instruments should not be produced equal to the best that the world has to offer.

If in some classes British scientific instruments fall somewhat below the standard of foreign instruments, in others they are unquestionably superior. It would be invidious to particularise minutely, but the following statement by the manager of a British firm of optical instrument makers, writing in the *Morning Post* of October 1 last, may be given in illustration:—

"In connection with the manufacture of optical instruments for research, a search has been made throughout the premier journals of the world devoted to physical science for the years 1910 to 1914. In each of them, in the Proceedings and Transactions of the Royal Society and in the *Philosophical Magazine* (Great Britain); in the *Physical Review* and the *Astrophysical Journal* (United States); in the *Comptes rendus* (France); and in the *Annalen der Physik* (Germany), there were without exception more references to instruments made by my firm here in London than to those of any other makers whatsoever. In the case of the *Annalen der Physik* there were 50 per cent. more references to my firm than to any other, the firm mentioned next in order of frequency being a well-known German one."

Facts like these are not so widely known, even among British scientific workers, as they should be.

A statement—originally, it may be, true in substance—is made that a certain type of foreign instrument is superior to any other; the statement grows to a legend and lives long after changes and developments have rendered it false or, at least, misleading; and the British instrument has to overcome much inertia of prejudice and fashion before it can secure the recognition which its merits deserve. It would be well if the leading scientific users of instruments would review from time to time their judgments of the quality and performance of instruments, so that improvements in British instruments may receive early recognition and the British manufacturer not be prejudiced by a belated preference for foreign instruments.

The present condition of the British scientific instrument industry is gravely compromised by the abnormal state of the international rates of exchange. Whatever legislative measures may be employed to help the industry over a difficult period, there can be no doubt that the most potent means of promoting the production of British scientific instruments equal to the best that the world can offer—a matter in which manufacturers and users are alike concerned—lies and must lie in an intensive and extensive application of scientific research to the fundamental scientific problems and the current technique of the industry. Other countries, notably Germany and America, we may be sure, will not neglect this. The leading British scientific instrument manufacturers have recognised the primary and paramount importance of scientific research. The British Scientific Instrument Research Association was founded in 1918, and its third annual report, which was reviewed in NATURE of November 17 last, gave ample evidence of the value to the industry of such an institution. It is true that, as is stated in the fifth annual report of the Committee of the Privy Council for Scientific and Industrial Research, "research cannot be expected to produce results at short and regular intervals"; but the Association has already produced results of immediate practical application and of economic benefit to the industry without losing sight of the fundamental researches, necessarily slower in coming to fruition, on which the progress of the industry must be based. Nor should it be overlooked that the co-operative research of the Association not only does not supersede, but stimulates and assists, the research work of individual firms which are members of the Association.

Moreover, where the Association, in view of its duty to the pressing needs of the industry, is unable to explore all the by-paths of pure scientific research that are opened out, arrangements have been made for extra-mural researches in the universities or kindred institutions for the prosecution of these relevant but more remote investigations. It must be remembered, too, that the Association, as the scientific centre of the industry, provides a needed *liaison* between the manufacturers and users of scientific instruments in this country, so that, on one hand, the manufacturers may be more fully informed of the needs of the users, and, on the other, the users may better appreciate the limitations imposed on manufacturers by the nature of materials and industrial conditions.

If the manufacturers will follow with patience and persistence the path of scientific research on which they have already made significant progress, there is every reason to hope that British scientific instruments generally will be, as many now are, supreme.

The History of Zeeman's Discovery, and its Reception in England.

Verhandeligen van Dr. P. Zeeman over Magneto-Optische Verschijnselen. Pp. xv + 341. (Leiden: Eduard Ijdo, 1921.)

TWENTY-FIVE years ago Dr. Zeeman, working at Leyden in the laboratory of Prof. Kamerlingh Onnes, achieved the epoch-making discovery which is now so abundantly familiar to physicists. Almost simultaneously he was appointed professor of physics at Amsterdam. To celebrate these events a volume of his collected papers, bearing on this branch of magneto-optics, has been published, under distinguished editorship, with a portrait and a few editorial notes and minor corrections.

This is the volume under review. It is a tribute to Prof. Zeeman from his friends and colleagues, on the occasion of the twenty-fifth anniversary of the announcement of his discovery to the Amsterdam Academy of Sciences on October 31 and November 28, 1896. It has an introduction in Dutch, dated October, 1921, which is signed by H. A. Lorentz, H. Kamerlingh Onnes, I. M. Graftdijk, J. J. Hallo, and H. R. Woltjer.

In commending this volume I would say that no one need be deterred from attending to it by reason of ignorance of the Dutch language: for our Dutch friends, with their well-known consideration, are polyglot in their publications, and there is plenty of English as well as French and German in the book.

The volume being mainly one of historical and permanent interest, it seems fitting to receive it with acclaim and to supplement it by an account

of the reception and speedy appreciation of the discovery in England. For in a quarter of a century a new generation of physicists has arisen, many of them so intently occupied with their own admirable investigations that perhaps the origin of much of our present knowledge of Nature is liable to be submerged. Especially may they fail to realise the anticipations of the great theorists, which enabled a little seed-fact to fit immediately into its cranny and quickly to develop magnificent blossoms.

As to its reception here, the beginning was extremely modest, and may be narrated thus: On December 24, 1896, there appeared in NATURE, vol. 55, p. 192, the usual report of a meeting of the Royal Academy of Sciences of Amsterdam, and in a paragraph abstracting a number of other communications to that society the following sentence occurs:—

"Prof. Kamerlingh Onnes communicated two papers: (*a*) by Dr. Zeeman, on the influence of magnetisation on the nature of the light emitted by a substance. Pursuing a hint given by Faraday, several experiments were tried. The principle was this: the light of the electric arc, being sent through a heated tube containing sodium vapour, is analysed by a Rowland's grating. The tube is placed between the poles of an electro-magnet. When acted on by the magnet, a slight broadening of the two sodium lines is seen, tending to show that forced vibrations are produced in the atoms by the action of magnetism; (*b*) by Dr. J. Verschaffelt on capillary ascent," etc.

This sentence, included in a long paragraph, was probably the first announcement in England; but it was so inconspicuous that it could scarcely have attracted much attention, had not Sir Joseph Larmor, this year's Copley medallist, been on the look-out for an effect of this kind. He had previously perceived that such a result was necessary theoretically; a fact which is demonstrated by, among other things, the following passage reproduced on p. 203 of his book, "Æther and Matter":—

"Each absorption line say of sodium vapour in a magnetic field will thus be more or less widened, and its main position also slightly shifted but only to a higher order of small quantities: and the same will apply to each line in the emission spectrum."

Larmor had indeed gone on to calculate the amount of displacement or broadening to be expected, and had found the effect too small to be observed; for, like everyone else at that time, he considered that the radiating body must be an atom or part of an atom with an $e/m = 10^4$. So directly Zeeman got an effect, and found that the e/m was really of the order 10^7, Larmor perceived that, not the whole atom, but the charge only—the electron part of the ion, or an electron itself—was a free radiator, and wrote to me suggesting that I should examine and confirm the result. In a week I had done so, with such appliances as were to hand; though not without sufficient difficulty to make me realise the naturalness of Faraday's failure to see anything—he being wholly unguided by theory—and to admire the skill of Zeeman in detecting the effect.

Prof. Zeeman must soon afterwards have communicated his observations to the Physical Society of Berlin; for in NATURE, vol. 55, p. 347, is a translation of a short paper by him, dated from Amsterdam and thanking Prof. K. Onnes for his interest in the work.

The first official notice in England occurs in the Proceedings of the Royal Society for February 11, 1897, when a note by me entitled "The Influence of a Magnetic Field on Radiation Frequency" was received and read on the same day. It gives an account of my repetition of Zeeman's experiment and directs attention to Prof. Lorentz's theory of it, together with his brilliant prediction about polarisation of the modified lines, and its experimental verification (see Proc. Roy. Soc., vol. 60, p. 513). It is followed, on p. 514, by a theoretical note by Sir Joseph Larmor, in which he emphasises the "electron" aspect of the matter, and its reciprocal relation to Faraday's first magneto-optic effect. He also directs attention to previous memoirs by Helmholtz in 1893, and by Lorentz in 1892 and 1895, especially the former; and he cites p. 813 of his own splendid Memoir in Phil. Trans., A, 1894.

I also communicated a much longer article to the *Electrician* for February 26, 1897, vol. 38, p. 568, under the heading, "The Latest Discovery in Physics": an article which I should like to reproduce here, for I venture to say that portions of it are worthy of reference by anyone interested in scientific history. The freedom with which we all spoke of electrons and their motions in those days rather surprises me, seeing that the unit charge was not isolated and clinched until 1899. But, of course, the theoretical work of Dr. Johnstone Stoney and others had long preceded this date.

There was no excuse for not fully understanding the main perturbations of spectrum lines when once the idea of electrons revolving like satellites in regular orbits, obedient to astronomical laws, had been grasped; for Dr. Johnstone Stoney's remarkable paper, entitled "On the Cause of Double Lines and of Equidistant Satellites in the Spectra of Gases," was in my possession. (It will be found in the Transactions of the Royal Dublin Society for 1891, vol. 4, Series II., pp. 563–608.)

But the difficulty was that at that date we all—

except perhaps Larmor and Lorentz—thought of an electron as of something attached to an atom, making it an ion, in accordance with Faraday's electrolytic ideas; and the notion of a free satellite electron, inside the boundary of an atom, was of later growth. In fact, it was a development largely brought about by Zeeman's discovery.

Parenthetically I may remark that there is some risk of Dr. Stoney's contributions to science being overlooked, partly because the Transactions of the Royal Dublin Society are not so readily accessible as some other publications, and partly because he expressed himself in terms and ways not always in accordance with ordinary custom. Let me put on record here, therefore, that, at that early date, 1891, he examined dynamically the problem of satellite electrons perturbed from a simple orbit by unknown forces. He deals with elliptic, apsidal, and precessional motions, with periodic changes in each, and clearly depicts the double and treble and quadruple lines which would result.

He is not dealing with perturbations excited by some definite outside physical cause, such as a magnetic field applied to the source, but with the normal series of lines observed by spectroscopists—Balmer, Kayser and Runge, etc.; and the inference he draws is that many of the known groups can be accounted for on the analogy of astronomical perturbations. The problem he set himself is thus worded (p. 569):—

"We shall accordingly, for the present, regard certain points in the molecules of the gas as acting dynamically on an æther capable of receiving and transmitting only transverse vibrations, and we have to inquire what motions of these points within the molecules would impart to the medium the oscillations which correspond to the observed lines in the spectrum."

To return from this digression. Whether on account of my article in the *Electrician*, or because I had written direct to Prof. Zeeman (probably for the latter reason), he sent me the MS. of a finished paper of his, giving the experimental details and also his version of Lorentz's theory developed on equations like those of the Foucault pendulum; and this paper I at once communicated to the *Phil. Mag.* for March, 1897 (vol. 43, p. 226), adding a brief footnote to say that I had verified the author's results so far as related to emission spectra and their polarisation. This memoir is now reproduced as the first in the volume of Zeeman's collected papers just issued, and it is printed in four languages—Dutch, English, French, and German; but the English and other versions contain an appendix, not in the original Dutch, giving an account of the attempts made long ago by Faraday, and likewise a theoretical anticipation by Prof. Tait in 1875 (an anticipation based on Kelvin's general theory of magneto-optic rotation), together with the record of a contemporary failure experimentally to detect any such effect. This appendix also removes from competition some apparently similar but not identical observations made by a M. Fievez.

It is of interest to find that in this remarkable and fundamental paper by Prof. Zeeman the possible effect of solar magnetism on the sun's radiation is indicated as a subject for inquiry—a development afterwards so brilliantly followed up by Prof. Hale.

In May, 1897, I communicated another note to the Royal Society (Proc. Roy. Soc., vol. 61, p. 413), in which details of the appearance of the lines are given, and the curious complexity of some of them; also, which surprised me, a difference between the behaviour of the components of the pair of sodium lines. The red cadmium line was also examined, and other spark spectra. The substance of this paper is reported in NATURE, vol. 56, p. 237. And in the same month (on May 19) I exhibited the effect at the Royal Society soirée, as appears from the following entry in the Year-book for 1897, p. 119:—

"*Demonstration of Zeeman's Discovery of the Broadening of Spectrum Lines by the Action of a Magnetic Field on the Source of Light. Exhibited by Prof. Oliver Lodge, F.R.S.*

"Sodium lines produced by an oxyhydrogen flame between the poles of a powerful magnet are examined by means of a Rowland concave grating (the one with which Mr. George Higgs photographed the solar spectrum), and can be seen to broaden whenever the magnet is excited. A nicol or other analyser shows that the light of changed refrangibility is polarised, as it would be if the source of radiation consisted of revolving electrified particles whose motion is accelerated or retarded by magnetic lines of force through the plane of motion.

"Recent Observations.—By reason of reversals, the usual appearance of each sodium line is as if it were doubled; the magnetic field makes it appear triple, or even quadruple. A nicol properly oriented removes the magnetic effect. D_1 shows it more sharply than D_2. The new lines intrude into the middle, after the fashion of Newton's rings."

It may seem from this that the observation of doublets and triplets, as indicated by the theory, was made by me; but that I disclaim, as appears in the volume under review, p. 101, since, though I saw something like the real effect, I did not apprehend it clearly as a pure precessional effect (akin to that which Dr. Johnstone Stoney had worked out long ago), and was inclined to suppose that the magnetic acceleration and retardation of frequency, acting on a random collection of molecules, would be likely to

cause a confused broadening (see the *Electrician* of February 26, 1897, vol. 38, top of p. 569). I was still too much influenced by the idea of random atomic motions, instead of precise electronic orbits.[1] The real effect, as perceived in advance by Lorentz and realised clearly by Zeeman, was much sharper and more beautiful than that, and my suspicion of a more complex or mixed effect was unnecessary; the simple Lorentz theory served, just as cited in that same article of mine in the *Electrician* (except that I made a slip and gave a value for the perturbed frequency which I correct in the second following issue, p. 643 of the same vol. 38. Some remarks on e/m, interesting from an historical point of view, will also be found in that issue, and an extremely short formulation of the theory, thus: "Magnetised change of centripetal force, $eHr\omega = mrd\omega^2$, whence $d\omega = eH/2m$." Here also is the record of a temporary slip about the sign of the effect, made by Zeeman himself, for he at first announced that the radiating particle was a *positive* charge).

At the same time, a pure doubling or a tripling, characteristic of a truly circular or elliptic orbit perturbed by an apsidal or a precessional motion, is not the last word; for, though this is the standard of simplicity, each line in the spectrum is liable to have peculiarities of its own, depending on the nature of the electronic orbit which is magnetically perturbed; and hence there is found, not indeed mere broadening, but a quadrupling, sextupling, and other varieties of effect, such as are now well known, but which I confess surprised me when first I saw their indications.

In the *Phil. Mag.* for December, 1897, is an important theoretical paper by Sir Joseph Larmor, "On the Theory of Magnetic Influence on Spectra, and on the Radiation from Moving Ions." Towards the end of this paper he deduces his fundamental expression for radiative power, as proportional to square of charge and square of acceleration. Non-radiation from charges moving at uniform speed *seems* to be indicated—which would be very convenient in making unperturbed atoms permanent—but unfortunately centripetal acceleration seems equally destructive to their constitution, were it not for the modern device of quanta.

In this same volume of the *Phil. Mag.* (vol. 44, pp 55 and 255) are two additional papers by Zeeman, also reproduced in the book under review, constituting the real publication of the occurrence of definite doublets and triplets in the magnetic field; and they are followed in this book by another one giving metrical results obtained photographically.

Photographic records of the effect were, indeed, tried for by other experimenters, though without success (see Nature, vol. 56, p. 420). In Nature, vol. 57, p. 173, however, Thomas Preston reports complete success, in Dublin, with a fine grating belonging to the Royal University of Ireland, mounted in accordance with Rowland's geometrical-slide design. But on p. 192 of the same volume a meeting-report shows that Zeeman had exhibited specimens of similar photographs at the Amsterdam Academy a month earlier; and he was now able to apply the photographic method to the obtaining of more exact measurements, as mentioned in the *Phil. Mag.* for February, 1898, p. 197. See also Preston, p. 325 of the same volume (vol. 45), by whom a plate showing the various appearances with great distinctness is submitted. A few pages further on (p. 348) is a communication, which still further emphasises complexities and individual peculiarities in the magnetised lines, by Prof. Michelson, who here begins to apply to them his remarkably powerful "visibility" test, which was first elaborated in the *Phil. Mag.* for September, 1892 (vol. 34, p. 280), as a sequel to his earlier more theoretical paper in April, 1891, and is now employed with such skill and brilliant success at Passadena to measure the diameter of stars.

In further papers by Zeeman the spectrum of *iron* is specially examined, and a lack of symmetry detected in some of its lines. And presently the resolving power of the Michelson echelon is pressed into the service for the further examination of details, with results which are described and expounded through the remaining 200 pages of this interesting memorial volume.

The extreme importance of Zeeman's great discovery, and the admirable way in which he worked it out with the inspiring theoretical assistance of Prof. H. A. Lorentz—so that theory and experiment went hand in hand, as it is to be wished they did more often—may be allowed to justify and excuse this somewhat personal welcome of its twenty-fifth anniversary by an English physicist.

Oliver Lodge.

[1] Incidentally and generally, it cannot be unknown, but it seems to be sometimes overlooked, that every *regularity* tends to evade the equipartition of energy difficulty: for Maxwell's proof requires the motions to be not only interchangeable, but also completely random.

The Kaiser Wilhelm Institute.

Festschrift der Kaiser Wilhelm Gesellschaft zur Förderung der Wissenschaften zu Ihrem zehnjährigen Jubiläum Dargebracht von ihren Instituten. Pp. iv+282. (Berlin: Julius Springer, 1921.) 100 marks.

The Kaiser Wilhelm Gesellschaft zur Förderung der Wissenschaften owes its origin to the action of certain leading industrialists

connected with the principal chemical establishments of Germany who were concerned as to the future of science, and more particularly of physical science, in that country. In their opinion the German university system no longer sufficed to meet modern requirements in regard to research in abstract science, and they suggested to the All Highest the creation of an institution which should be wholly and exclusively devoted to research, and should be staffed by men of proved capacity to undertake its successful prosecution. They so far succeeded in impressing the Emperor with their views that he in his turn suggested to his memorialists, and to others who sympathised with them, that they should themselves find the money needed to endow and equip the contemplated institution, and, by way of showing his practical interest in the project, he further indicated what amounts the several industrial concerns, or their representatives, might be expected to contribute.

The society was duly inaugurated with all the pomp and ceremony which usually characterised any function or enterprise with which William II. desired that his name should be specially associated, and the occasion was further made memorable by the address which the late Prof. Emil Fischer then delivered.

The institution thus established at Berlin-Dahlem has now been in existence for ten years, and it has been thought expedient by those connected with its working to celebrate its "zehnjährigen Jubiläum" by the publication of a "Festschrift." By us a jubilee is usually understood to mean the celebration of a period extending over fifty years, corresponding to the Grand Sabbatical Year of the Jews, although there has grown up a certain laxity in the use of the term which is frequently held to denote a season or occasion of public festivity, which may or may not recur at stated periods. What were the precise reasons in the minds of those responsible for the management of the institution which led them to direct public attention to it at this particular time can only be surmised, for there is nothing by way of preface or introduction to the "Festschrift" to inform us.

The celebration of a jubilee after so short an interval as ten years, during half of which time the work of the society was seriously disturbed and hindered by the war, has, when we have regard to the unsettled condition of Germany, somewhat the appearance of a political move. It will not be forgotten that it was at the Kaiser Wilhelm Institute "for the Promotion of Science" that Geheimrat Haber made his experiments on poison gas, prior to the Battle of Ypres, which initiated a mode of warfare which is to the everlasting discredit of the Germans. We are not aware that the present Government has shown itself inimical to the interests of science; unlike Coffinhal, it has never pronounced "La République n'a pas besoin de savants." On the contrary, Germany realises that she owes too much to science during the last half-century, and especially during the critical years of the war, for her to be unmindful of its benefits. Whatever form of government she may ultimately adopt, she is too much beholden to science to neglect its claims, and there is no reason to believe that these claims will be less adequately met by a republic than by a monarchy. At the same time, it cannot be doubted that the impoverishment of the country will react disastrously upon the position and prospects of all institutions which, like the Kaiser Wilhelm Society, are dependent upon public funds or private munificence.

Although we are prepared to welcome every sign of renewed scientific activity in Germany, it cannot be said with strict regard to truth that this "Festschrift" is in any sense epoch-making. There is certainly nothing jubilant about it. It is divided into two main portions, one of which, consisting of thirty-three short papers extending in all over 243 pages, deals with natural science; the other, consisting of four papers, is concerned with the science of history, and is comprised within eighteen pages. Of the natural science papers the greater number relate to relatively small points of bio-chemistry; the others are about equally divided between subjects of pure and applied chemistry and physical chemistry. Among the contributors are Abderhalden, "Zur Kenntniss von organischen Nahrungsstoffen mit spezifischer Wirkung"; Armbruster, "Tiere als Tierzüchter—Eine Erklärung ihres Sozialismus"; Einstein, "Eine einfache Anwendung des Newtonschen Gravitationgesetzes auf die Kugelförmigen Sternhaufen"; Haber, "Uber Wissenschaft und Wirtschaft"; Carl Neuberg (who edits the volume), "Uber den Zusammenhang der Gärungserscheinungen in der Natur"; Prandtl, "Neuere Einsichten in die Gesetze des Luftwiderstandes"; and Stock, "Die Chemie des Leichtflüchtigen." Many of the papers are short historical summaries of the present state of knowledge on the particular point dealt with. Some of them, in fact, read as if they were amplified excerpts from university courses of lectures. Others are simply *réchauffés* of work which has been published in detail elsewhere.

The papers on the science of history comprise one by von Harnack on "Die Apokalyptischen

Reiter," and—curious association—two short notices relating to the Emperor William I. These deal with the Frankfort Congress of 1863, and with episodes in 1870 at Ems, and at Sedan. The notes of the conversation with the French Ambassador Benedetti at the former place (July 13 and 15, 1870), and with Napoleon III. at the latter place (September 2, 1870), are of historical interest, and are among the few papers of permanent value contained in the book.

The price of the brochure, which is issued in paper covers, is stated to be 100 marks, which, considering the present value of German currency, is not excessive, however significant of Germany's financial straits. The book is admirably printed on excellent paper, and is suitably illustrated. It does credit, in fact, to the eminent firm by which it is published. The war and its consequences have evidently had no detrimental effect on the typographical excellence of book production in Germany.

Fish Preservation.

Fisheries—England and Wales. Ministry of Agriculture and Fisheries. Fishery Investigations: Series 1, Freshwater Fisheries and Miscellaneous. Vol. 2, No. 1, *The Methods of Fish Canning in England.* Pp. 25. (London: H.M. Stationery Office, 1921.) 2*s.* 6*d.* net.

THE development of methods of preserving fish was a matter of national importance during the war, and the present account is founded on investigations started in that period. The fish used for canning are mostly surface-feeding and living fish, such as sprats (or bristling), sardines (or pilchards), tunny and bonito, herring and mackerel, the only other fish of any importance being the salmon caught in America on its migration to fresh water for breeding. Of British fish there is a great excess of herring in the normal fisheries, and, given suitable fishing gear, large quantities of sprats can also be obtained on all coasts. Mackerel are at times abundant, but there is little certainty of heavy catches year by year; pilchards are local to Cornwall, and the immature forms (sardines), so extensively tinned in France, Spain, and Portugal, are not caught in quantity. There was one British sprat cannery before the war, but herrings were put up at the great herring ports in oil or with tomato, the product being in some cases excellent. Excess sprats were generally used for manure, while herrings were salt-pickled and barrelled for export, the price being two or three for a penny. The latter is an "unspeakable" product, which has never found favour in this country, and fresh methods of preservation are urgently requisite for the utilisation of herrings as a cheap form of food. The markets, too, of Central and East Europe, which took most of this product, are disorganised, and it is doubtful whether they can ever be recreated, as there would seem to be a real improvement in Continental taste, brought about by the temporarily improved food conditions of the war.

The success of different kinds of fish as canned products depends largely on the fat which lies under the skin and between the muscles. Salmon is canned or frozen in air (dry frozen) on the Pacific coast almost immediately when caught, certainly before *rigor mortis* has set in; the same is, to some degree, true also of the Norwegian sprats (bristling), of which there are about eighty factories in operation. The difficulty in Great Britain is that no port has a herring or sprat season extending through more than three or four months, and a factory with modern appliances and trained packers cannot be run profitably for such a short season. The fish required at other times must be brought in by rail, and this doubles the cost, while the actual fish has passed through its *rigor* and is deteriorating. It would seem necessary to get the fish as fresh as possible and to discover some method of preservation in bulk for subsequent packing, the process being one which would in no wise alter its composition or flavour.

Experiments with brine freezing and subsequent cold storage are described, but difficulty was experienced in the caking of sprats into masses and the salting, due both to the small size of the fish and to an excessive cold-store temperature "just under 30° F." Both these difficulties might perhaps be got rid of, but the total cost of the actual freezing, storage, transport, etc., would probably average 3*d.* per lb., which only a first-rate product could bear. Unfortunately, British sprats, as at present caught, are shown to be by no means such a product, being indeed much inferior to the Norwegian. According to the tables, they varied in fat from 5 to 23 per cent., protein being 15 to 20 per cent., ash about 1·5 per cent., the rest being water, which, with fat, roughly forms 80·5 per cent. The problem is to catch sprats of the right composition for pickling. The English fish is winter and spring caught, while the Norwegian fishery is in summer and autumn. The reproductive cycle has doubtless something to do with the quality, but little is as yet known of the life-history of the English fish. The difference lies probably, not in the fat contents, but in other

qualities, the winter fish being of inferior taste and texture. Clearly we must either continue to pack a second-rate product, or discover where our sprats go to in summer, invent methods of catching them, and finally adopt more "fastidious" methods of handling, all of which Dr. Johnstone clearly considers could be accomplished by further research. In contradistinction to the sprat our summer herring is said to be second to none.

After canning the flavour of the fish improves notably, the raw taste disappearing, the bones softening, and the flesh breaking easily; this is what is called "maturation," and the time required is from six months to as many years to give the best product. No suggestions or experiments to ascertain the cause of this proved satisfactory. It would not seem to be autolysis, for storage at a temperature of 37° C. did not hasten the process. Bacterial change is considered more likely, as spores can withstand a temperature of 150° C. if present in oil. Catalysis, however, cannot be ruled out, as the tin of the container is always to some degree dissolved. The whole question of "maturation" in respect to all canned foods is, as Dr. Johnstone says, "of huge practical importance—and of remarkable obscurity." It is certain that no commercial product can be stored for from three to six years and then sold cheaply.

The whole report is immature, in that the investigations were never made on a sufficient scale to be economically of value, and were prematurely closed down. It seems doubtful whether they can profitably be restarted until basal investigations, such as on the nitrogenous composition of the protein of fish in respect to phases of reproductive activity and to the formation of fat, are completed. On freezing and maturation the Food Investigation Board,[1] in the midst of other investigations, had been conducting researches for three years, but it is quite clear that there is plenty of room for less "directed" researches. Either the Fishery Boards should take up the whole problem, directly or through the Food Investigation Board, and vigorously prosecute it—even employing bounties if necessary—with a determination to create a new industry of value to an island nation, or drop it altogether. The Scottish Fishery Board made the export of salt herrings—in 1913 8,795,232 cwts. of value 5,331,042*l.*—a valuable British industry, by pursuing a consistent, steady policy through several decades. In the twentieth century Government officials seem to have little of the imagination required or to be afraid of the fluctuations of political affairs. They need not be, for surely these developments are national and not political, and such as "the man in the street"—and in the Commons—requires.

J. STANLEY GARDINER.

[1] See Report for 1920. (H.M. Stationery Office.) 1*s.*

Our Bookshelf.

The Microtomist's Vade-Mecum: A Handbook of the Methods of Microscopic Anatomy. By A. B. Lee. Eighth edition. Edited by Prof. J. B. Gatenby, with the collaboration of Prof. W. M. Bayliss and others. Pp. x + 594. (London: J. and A. Churchill, 1921.) 28*s.* net.

THE new edition of this well-known work of reference has been completely revised by Prof. Gatenby, who has had the assistance of experts in various branches of microscopical technique, and the result is a volume which is practical, critical, and thoroughly up-to-date. Prof. W. M. Bayliss has rewritten the chapter on staining, and his concise account of the nature of staining and of differentiation gives a clear conception of the physico-chemical facts on which these processes are based. Dr. C. Da Fano has been responsible for the five chapters on neurological technique, which form 100 pages of the book and contain many suggestions drawn from his extensive experience. Dr. A. Drew has rewritten the section on Protozoa, which, in addition to the methods for fixation, staining, etc., gives an account of cultural methods for amœbæ; Dr. W. Cramer contributes a dozen pages on the micro-technique of fatty substances, including a useful summary of the methods to be employed in a complete histochemical investigation of fatty cell-inclusions; and Mr. J. T. Carter has revised the account of methods for the study of teeth and bone. The remainder of the work has been in Prof. Gatenby's hands, and the sections on fixation, chromatin, nucleoli, mitochondria, and the Golgi apparatus are especially noteworthy and helpful in suggestions; mention should also be made of the short account of methods of tissue culture *in vitro*, which, in the hands of Ross Harrison and his successors, have given such remarkable results. The last chapter has been written for the beginner and gives clear directions for carrying through the preparation of a whole mount of a Daphnia, for making sections of muscle or other tissue of a vertebrate, and for preparing a tadpole for serial sections.

Two recent methods for staining bacteria have been introduced to help those who may be doubtful whether certain bodies in tissue are or are not bacteria. Having gone so far, the editor might perhaps consider whether he could include in the next edition the methods for the study of spirochætes which zoologists nowadays frequently find it necessary to examine. Under Annelids a reference to the preparation and mounting of chætæ would also be a useful addition.

The editor and his collaborators are to be warmly congratulated on the production of this thoroughly sound and practical guide, useful alike to students and to research workers.

A French-English Dictionary for Chemists. By Dr. Austin M. Patterson. Pp. xvii + 384. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1921.) 18*s*. net.

THE present volume is a companion work to the author's "German-English Dictionary for Chemists," and is likely to meet with an equally favourable reception. A practical test, working through original papers in organic chemistry, inorganic chemistry, and technical (engineering) chemistry proved the usefulness of the dictionary; only on the engineering side were a few deficiencies found. Chemistry has several other sciences on its borders, and this is recognised practically by the inclusion of some biological and botanical terms. The addition of technical words from mathematics, geology, and engineering, with more words from physics, botany, biology, and medicine would widen the scope of the book without necessarily increasing its bulk. It is stated in the introduction that "words of the same or nearly the same spelling in the two languages are defined even when the meaning is exactly the same as in English." This appears to the reviewer as a defect; the space might be better utilised in the direction just indicated. Thus, taking a page (368) at random, out of seventy-eight words sixteen have identical spellings and meanings; of the remainder, twenty-one are practically the same, and the obvious translation is the correct one, such as *uniforme, unimoléculaire, uranyle, ultramicroscopique.*

Handbuch der Holzkonservierung. Edited by Ernst Troschel. Pp. xi + 540. (Berlin: Julius Springer, 1916.) In Germany, 18 marks; in England, 54 marks.

TWELVE authors, comprising engineers, architects, foresters, and professors, have produced this comprehensive text-book, which contains the result of the latest investigations until 1916, on the preservation of wood. The book is clearly written and well illustrated. It contains references to most of the literature that has been published on the subject, in English as well as in German, and frequently discusses processes and materials used in England, India, the United States, etc.

The matter is arranged as follows: After an introductory chapter on the structure, function, and growth of wood and its tissues, part 1 deals with the destruction of wood by fungi, animals, and other agents. Dry-rot caused by Merulius, Lenzites, and other fungi, and the numerous injuries due to insects and marine borers, are treated at considerable length. The second part discusses the methods that are actually employed in preserving wood. These are very numerous, and most attention is paid to the processes involving impregnation with antiseptics, applied with or without pressure. The materials and machinery used are described in detail. The history of the subject is illustrated by a list of all the substances that have been tried from 1700 to 1876, with the name of the inventor and mode of application in each case.

The third part is concerned with the care of wood put to use under various conditions, as in the open air, under water, inside houses, etc. The influence of moisture and the action of chemical preservatives on the strength and durability of timber are briefly treated, most reliance being placed on Janka's experiments at Mariabrunn. The fourth part is very practical, containing special articles by engineers on the problems connected with the maintenance and preservation of the wood used in mines, railways, telegraphs, docks, bridges, ships, houses, street-paving, etc. An appendix, pp. 498–540, gives a list, classified under forty headings, of the most important patents in connection with the preservation of wood that have been taken out in all civilised countries.

Liquid and Gaseous Fuels and the Part they Play in Modern Power Production. By Prof. Vivian B. Lewes. Second edition. Revised and edited by John B. C. Kershaw. (The "Westminster" Series.) Pp. xiv + 353. (London: Constable and Co., Ltd., 1921.) 12*s*. 6*d*. net.

IN his revision of Prof. Lewes's work on liquid and gaseous fuels, Mr. Kershaw has adopted the plan, dictated in part, no doubt, by the need for economy, of inserting new matter in the form of footnotes collected at the end of each chapter. Thus when Prof. Lewes ventures upon a definition of an atom, we are referred to a footnote some five pages further on for more modern views on the subject; this becomes irritating. Substantial additions have been made to the first edition, which was reviewed in NATURE of December 5, 1907, p. 98, in the form of information relating to the manufacture and use of power alcohol, and in the appendices, which contain accounts of fuel oil burners and vertical continuous retorts for gas manufacture, as well as extracts of recent statistics of oil fuel burning.

The Fixation of Atmospheric Nitrogen. By Dr. Joseph Knox. (Chemical Monographs.) Second edition. Pp. vii + 124. (London: Gurney and Jackson, 1921.) 4*s*. net.

IN the revision of his useful little monograph Dr. Knox has added brief accounts of the Haber process and of ammonia oxidation. The statement in the preface that "comparatively little work of importance on the theoretical side has appeared since the first edition of this book was published" is scarcely justified, and the fact that, of the 169 references to the literature which are given, only about fifteen are of dates later than 1913 is not what one might expect. The account of the Serpek process, for example, is quite out of date, and no reference to Serpek's later publication is given. The book will no doubt prove as useful to students as the first edition, and is a readable introduction to a most important subject.

Letters to the Editor.

Generalised Lines of Force.

LET me direct attention to a notable paper by Prof. E. T. Whittaker, in the Proceedings of the Royal Society of Edinburgh for November last.

It has often been discussed whether electric or magnetic lines of force were the more fundamental, and which might be regarded as the "cause" of the other; a discussion rather like the old controversy as to the direction of vibration in a polarised beam of light. Maxwell's theory satisfied the disputants by making both directions equally important.

In this paper Whittaker extends Faraday's theory of lines of force to electromagnetic activities in general, expressing the complex facts by aid of the space-time continuum of Minkowski, whereby any form of kinematics can be expressed as a sort of four-dimensional statics. The solenoids of Faraday are shown to be special cases of a more general kind of surfaces, called *calamoids,* which reduce to ordinary electric lines of force when the field is purely electrostatic, while they reduce to ordinary magnetic lines of force when the field is purely magnetic; so that the Faraday electric and magnetic lines are not two distinct and (as it were) rival things, but two limiting cases of the same thing. The essential solenoidal condition—strength inversely as cross-section—is retained if, instead of electric or magnetic force separately, the contra-variant $\sqrt{(E^2-H^2)}$ is employed, and if the cross-section is that of a calamoid.

Ordinary equipotential surfaces, whether electric or magnetic, are seen to be special cases of an "electro-potential" or "magneto-potential" [? ether-potential] surface, which reduces to one or other of them whenever the field becomes static. These electro-potential surfaces, in general, exist in the four-dimensional world of space-time; but when the field is static each surface is wholly contained within three-dimensional space, and is an ordinary equipotential surface.

The property of the Faraday lines of force, that they are everywhere perpendicular to the equi-potential surfaces, is shown to be a case of the more general theorem that the calamoids are everywhere "half-orthogonal" to the electropotential surfaces; (half-orthogonality being the four-dimensional analogue of three-dimensional perpendicularity).

In electrostatics, the total strength of all the Faraday tubes which issue from a closed surface containing no electric charge is zero; similarly, in general radiation-fields, the total strength of all the calamoids which cross a closed surface is zero. This theorem provides an intuitive geometrical integration of the Maxwell-Lorentz equations of the electromagnetic field.

There are also elaborated generalised "divergence" and "curl" theorems, with a certain kind of absoluteness about them, since they are independent of the motion of any observer.

For much fuller and more trustworthy information Prof. Whittaker's paper must be referred to. He said something about it in Section A at the recent meeting of the British Association in Edinburgh, but I, for one, did not understand his meaning then, in the rush of Sectional procedure. The object of the present summary is merely to direct early attention to a paper which cannot be long overlooked.

December 28. OLIVER LODGE.

Units in Aeronautics.

WRITE the usual formula in aeronautics,

$$\frac{R}{S} = 23{\cdot}7\left(\frac{V}{100}\right)^2, \text{ lb/ft}^2,$$

in the Hospitalier notation, and the practical airman recognises that the resistance R, lb, over a surface S, ft², is at the rate 23·7 lb/ft² at a normal velocity of 100 f/s; and so on for any other velocity V, on the law of the square.

The airman pays no heed to any units except his foot and pound, and he has no use for any of the elaborate explanations of Mr. A. R. Low.

The factor 23·7 will be the result of experiment in the air-channel, reduced for air of standard conditions of barometer and thermometer on the ground.

But the air density is never measured in any of these experiments, and it is doubtful if the measurement has ever been carried out in any aeronautical laboratory.

In the early history of the Royal Society "weighing the air" was a favourite research. Charles II. bet Buckingham fifty guineas to one he would demonstrate the compression of air in his hollow walking-cane; but the other story of the fish in a bucket of water cannot be traced further back than Whateley, who is supposed to have invented it.

The air density arises in the formula of the treatise on aerodynamics on the idea that the formula is the expression of Newton's assumption that the resistance is due to the impact of inelastic air particles, as if air could be treated as a cloud of dust; and then at an air density w, lb/ft³, or better for calculation in thermo-aerodynamics, at a specific volume the reciprocal $C=1/w$, ft³/lb, Newton's formula becomes

$$\frac{R}{S} = w\frac{V^2}{g} = \frac{V^2}{gC}, \text{ lb/ft}^2; \quad \text{or } \frac{R}{S} = 2wh,\ h = \frac{V^2}{2g}.$$

In this treatment the Equation of Continuity is ignored; the air particles should stop dead and fall down in a heap at the foot of the aeroplane, to be swept up as dust.

Thus the mysterious factor 0·00237 of the treatise on aerodynamics is the equivalent of w/g, and with $g=32{\cdot}2$, f/s², this makes $w=0{\cdot}0763$, lb/ft³, $C=13{\cdot}1$, ft³/lb, so that this standard air bulks 13 cubic feet to the pound, in round numbers.

Another way of expressing the law is to write it in the equivalent form

$$\frac{R}{S} = \left(\frac{V}{H}\right)^2, \text{ lb/ft}^2,$$

so that H is the velocity at which normal resistance is 1 lb per square foot; then on the figures above $H=20{\cdot}5$ f/s, and this may be replaced by 20 in round numbers for practical calculation, making

$$\frac{R}{S} = 25\left(\frac{V}{100}\right)^2.$$

Flying over the ocean the velocity would be expressed in knots, K, and with 12 knots the equivalent of 20 f/s the formula is

$$\frac{R}{S} = \left(\frac{V}{20}\right)^2 = \left(\frac{K}{12}\right)^2, \text{ lb/ft}^2;$$

simple numbers easily remembered.

In all these calculations Perry's dictum must be respected: that the accuracy of a formula is only the accuracy of its most inaccurate part.

Here the index 2 of the velocity, adopted for simplicity of calculation, is the part most subject to doubt, and then at this rate of the quadratic law the above numbers, 23·7, 24, and 25, are all equally

suitable; their discrepancy is wiped out by small variation of air density or height of flight.

The practical airman will pay no heed to Mr. A. R. Low's elaborate explanation of the units employed in absolute measure (NATURE, January 5, p. 12). He has no use for poundal or slug units—fearful traps for the unwary and cause of great confusion of thought—and with the conceit to imagine they will pass current in the whole cosmos. But the rigour claimed for them is beginning to crack and show flaws under the merciless scrutiny of the new relativity.

Mr. Low is here coming to the rescue of the unhappy examinee, at the mercy of the whim of the examiner's text-book, and of the rigour demanded for the language employed there, ignored by the practical airman.

Divergence of language is never to disappear, as it seems, between science and engineering. The engineer refuses to budge when he finds he can arrive at a correct result in practice, and he ignores the rigour prescribed in the examiner's text-book as something to be thrown at the head of the examinee in his *conquête des diplômes*. G. GREENHILL.

Staple Inn, January 9.

Space and Æther.

THE relation of space and æther has been a subject of controversy. Three-dimensional absolute space has been regarded, before Einstein, as filled with a substantial æther. It is unnecessary to conceive the four-dimensional space-time of the relativists as so filled. If space-time is empty, is space also empty?

It seems to me that the crux of the difficulty is a wrong assumption that space-time is four-dimensional. Space-time is neither four-dimensional nor three-dimensional, but is two-dimensional. The orthodox analysis of the objective world down to the three fundamental entities of matter, space, and time has been incomplete. That which we call space also involves time. That which we call matter also involves both space and time. Thus what we call matter, space, and time should further be analysed as matter-space-time, space-time, and time where matter, space, and time with their new signification are fundamental entities. It is in this new sense that I shall use them hereafter.

Æther is the synthesis of space-times. It is matter-space-time. A synthesis is a petrified motion. We do not perceive the motion of æther because it is petrified. The motion in a space-time is independent of motion from space-time to space-time along the string that is æther. The so-called velocity of æther is not a change of space, but a change of matter.

Æther, being matter-space-time, partakes of the nature of all three. It has the density of matter, the rigidity of space, and the motion of time.

Æther is matter-space-time of no mind. The synthesis of matter-space-times of observing minds may be called hyper-æther—filling an absolute four-dimensional universe. Relatively to matter, æther is absolute. Relatively to mind, hyper-æther is absolute. The real is neither relative nor absolute, but is relatively absolute.

Einstein found that space-time was four-dimensional and that the universe was four-dimensional, and therefore argued that space-time was the universe. Therein lies his fallacy. His space-time is the two-dimensional section of a four-dimensional universe. There are two factors in evolution: persistence of identity and change of structure. As space-time is two-dimensional, its identity persists in the evolution from a three- to a four-dimensional universe. And as the world character changes, the internal structure of space-time changes. Einsteinian relativity is an anarchy. It marks a process of revolution, but does not attain a new position of stability.

Logic is not absolute, but is relative. The laws of logic of an absolute three-dimensional world are not the same as those of an absolute four-dimensional world. To study an absolute four-dimensional world we need a new logic, a new arithmetic, a new geometry, a new mechanics, and also a new science dealing not only with time as arithmetic does, not only with space as geometry does, not only with matter as mechanics does, but also with mind. On the recognition that time, space, matter, and mind contribute each a dimension to the universe I have been able to base an analytical geometry of the universe.

Space, in the sense of the arena of the three-dimensional universe, is matter-space-time, and may be regarded as filled with æther. The Euclido-Newtonian space-time and the Einsteinian space-time are non-material. But the latter is a stage of travail for the evolution of the former into a space-time with a new internal structure. The claim of the relativists to have demolished Euclid and Newton argues a want of the sense of historic perspective. Man does not progress by demolishing, but by building on, his past.

S. V. RAMAMURTY.

Trinity College, Cambridge, January 5.

Anisotropy of Molecules.

DIRECT evidence that the molecules of gases are not spherically symmetrical and are anisotropic in their properties is furnished by the recent experiments of Lord Rayleigh, who has shown that the light scattered by molecules is, in general, not completely polarised when observed in a direction transverse to the pencil of light traversing the gas. The method used by Rayleigh, and by those who have repeated the experiments establishing this effect is a photographic one, the track of the primary beam of light as viewed through a suitably oriented prism of Iceland spar being recorded on a plate with long exposures. In view of the great interest of the phenomenon, it occurred to the present writer that it would be worth while to attempt direct *visual* observation and measurement of its magnitude. The chief obstacle is, of course, the extreme feebleness of the unpolarised part of the transversely scattered light. This has, however, been successfully overcome. By using the strongest possible illumination (sunlight), securing a perfectly black background, and very carefully screening the eye from extraneous light, it has been found possible to detect with dust-free air at atmospheric pressure the non-extinction of the track as seen through a nicol at any orientation. With carbon dioxide the effect is quite conspicuous, and visual determinations of its magnitude have been successfully made by Mr. K. R. Ramanathan working in the present writer's laboratory.

A very interesting question arises whether it is possible to establish the same effect by observations on the polarisation of skylight. As is well known, there is a marked defect in the polarisation of skylight in a direction removed 90° from the sun, which is, however, in the main, due to dust and condensed water-vapour in the atmosphere and the diffuse lighting up of the sky by self-illumination and by reflection from the earth's surface. It occurred to me that the elimination of the effects due to these disturbing factors does not present insuperable difficulties. The reflecting power of landscape (about 0·08 when covered by vegetation) is known, and its effect is therefore calculable. Dust and low-lying mists may be prac-

tically eliminated by making the observations on a bright, clear day at a high-level station, and the self-illumination of the sky under the same conditions is very small *in respect of wave-lengths near the extreme red end of the spectrum.* The residual effect of self-illumination in these circumstances may be computed with sufficient accuracy by the method used by L. V. King (Phil. Trans. Roy. Soc., A, vol. 212, 1913), the uncertainties due to the neglect of the curvature of the earth and other simplifying assumptions in the calculation being then of little importance.

In order to obtain material for testing these ideas I made observations on the forenoon of December 4 last from the summit of Mount Dodabetta, in the Nilgiris (8750 ft. above sea-level), the sky at the time appearing beautifully clear, free from cirrus clouds, and almost completely black when seen through a deep red filter. The weaker component of polarisation was found to have 13 per cent. of the intensity of the stronger component. Diffuse illumination of the sky is capable of explaining only a part of this, a weaker component of about 8 per cent. intensity being indicated by the calculations. The residual 5 per cent. must therefore be ascribed to molecular anisotropy, and this is in agreement with the laboratory determinations of Rayleigh.

Observations on the molecular scattering of light in *liquids* made by the writer also show an imperfect polarisation attributable to anisotropy. Experiments in the same direction on the atomic scattering of light in crystals are being made, and an attempt is also in progress to discover the existence of an effect indicated by Sir J. J. Thomson's theory (*Phil. Mag.*, October, 1920), namely, the dependence of the results on the frequency of the scattered radiation.

C. V. RAMAN.

210 Bowbazaar Street, Calcutta, December 19.

The Resonance Theory of Hearing.

MAY I reply to Dr. Perrett's letter (NATURE, December 29 last), in which he makes the objection to the resonance hypothesis that it does not explain how we perceive when there are two tones of the same pitch sounding simultaneously?

It seems to me that Dr. Perrett has made two slight errors:—

(1) There must be, he writes, one result, unique and without alternative, when the tracing of the combined wave-form of any two notes of the same frequency is submitted to Fourier analysis.

But surely this cannot be true; for example, if in one case the two tones are 256 vibrations per sec. from an oboe and a flute simultaneously sounded, the relative amplitudes of the overtones found by Fourier analysis would be quite different from those found for the same tone sounded simultaneously on a violin and a cornet. Not only would the amplitudes of the overtones differ in the two cases relatively to the fundamentals, but they would differ also relatively to one another.

(2) Dr. Perrett proceeds: "If the ear acts as a kind of practical Fourier's theorem, it can perceive only one fundamental tone. But we invariably judge of the pitch of a note by its fundamental tone. If, then, we hear at the same time two notes of pitch n, the ear must be able to perceive also at the same time two fundamental tones of frequency n—that is to say, it must be able to perform an analysis which is not in accordance with Fourier's theorem."

Surely Dr. Perrett has omitted in the above reasoning to take into account the existence of beats, overtones, and phases. If these did not exist, and if the ear could still tell whether one or more than one instrument were contributing to a tone, then the resonance theory would have met with a serious difficulty. But overtones do exist, and they are known to differ for different instruments, also for one instrument in different circumstances, *e.g.* the human voice when sounding various vowels. The resonance theory, in that it explains the perception of overtones, even when their intensity compared with the fundamental is small, also explains how we can tell whether two different instruments are contributing to a tone or one only. But there are other clues; for besides that given by overtones, which in accordance with the resonance hypothesis the ear might make use of, viz. (*a*) if there were beats, due to the two instruments not being exactly in tune, the observer might infer that two were sounding, and not one; (*b*) if the sound-waves from one instrument reached the observer's right ear a little earlier (or later) than they reached his left, whereas those from the other instrument had different time relationships, he might infer that there were two sources of sound, from the observation that the two sources did not occupy the same position relative to his own plane of symmetry; and (*c*) if the sounds from the two instruments did not begin and end together the observer might get information from this also. All these possible methods of observation are compatible with the resonance theory, and therefore it is quite unnecessary to assume that the ear must be able to perform an analysis which is not in accordance with Fourier's theorem. It seems to me, therefore, that Dr. Perrett's objection must fail on all the above grounds.

May I take this opportunity of describing a fresh piece of evidence in favour of the resonance theory? Helmholtz showed, from physical considerations, that the coefficient of "sharpness of tuning" should be inversely proportional to the "persistence" coefficient in the case of resonators responding to tones of different pitch. This relationship does not postulate any special form of resonator, but appears to be a general rule equally as applicable to an electrical oscillating circuit as to a stretched string. If, then, it could be shown that the ear obeys this rule, it would be presumably very strong evidence indeed for the existence of resonators in the cochlea. The following table, calculated from observations by Mayer (published in *Amer. Journ. Sci.*, January, 1894), shows that the necessary evidence exists:—

A Mean tone in vibs. per sec.	B Per cent. difference of tone required to stop disonance (tuning factor)	C No. of vibrations performed during a subliminal silent interval (persistence factor)	B×C Tuning factor multiplied by persistence factor.
128	12·70	1·78	22·6
256	10·00	2·06	20·6
320	9·45	2·19	20·8
384	9·07	2·18	19·8
512	8·45	2·37	20·0
640	8·15	2·54	20·7
760	7·82	2·68	21·0
1024	7·22	3·01	21·7

Since multiplying tuning factor by persistence factor gives values nearly constant for different resonators (the average error is less than 3 per cent.), as shown in the last column in the above table, the tuning coefficient must be very nearly inversely proportional to the persistence coefficient. That is, the ear behaves quantitatively as it ought to do if it contained resonators.

I find a correction is necessary in my letter to NATURE of January 5. "Tide production" on line 20 should read "tide prediction." H. HARTRIDGE.

King's College, Cambridge.

A Curious Physiological Phenomenon.

IN Prof. Graham Brown's comments in NATURE of December 22 last on the letter with the above title, he points out that "the peculiarity of the present movement is that it is in the same direction as the original one." In this it resembles the sensory phenomena of positive optical after-images. Now these are periodically repeated after fairly strong stimulation, and it seemed worth while to look for such repetition in the present case. This is easily found, merely by increasing the time during which the hand is pressed against the wall up to about a minute until the whole arm feels tired. The rise and fall described occurs as usual; after a brief pause the arm again rises somewhat less vigorously, and a third much weaker rise may follow. This succession of movements does not always occur. In fact, in my own case even the first rise occasionally fails for no apparent reason.

I have found these repeated movements in the cases of colleagues who were not informed in any way what to expect. I am not familiar with the physiological theory of fatigue, but to a physicist these alternations of rest and activity inevitably suggest the accumulation and discharge of potential energy. I do not know if physiologists can find place for a (? cerebral) mechanism by which a thwarted stimulus can store up "strain" energy of appropriate kind, which after a brief interval is discharged by fulfilling its particular motor or sensory function. Further accumulation and discharge might follow, something after the fashion of the successive residual charges and discharges of a Leyden jar.

If this be so, positive visual after-images may have a similar origin. As is well known, the intensity of sensations only increases by equal increments when the exciting stimuli increase by equal ratios; thus strong stimuli fail, so to speak, to produce their full effect; there is inhibition and perhaps a storing of "strain" energy. Afterwards liberated, may this give rise in the sensory case to after-images, or with motor mechanisms to these involuntary muscular movements?

It may be added that the phenomenon can be produced in the leg by standing on one foot and pressing the outer side of the other against a wall, then allowing the leg to fall to the vertical with the foot still clear of the ground; after a short pause the leg rises laterally again. Or if the lower leg is drawn back so that its calf (or Achilles tendon) presses upwards and backwards against the edge of a heavy chair, and is then allowed to fall, the knee involuntarily flexes again after a very brief interval. In this case there is (with me, at any rate) a strong tendency for the pressure against the chair to cause acute cramp in the biceps muscle of the thigh.

Structures and Habits Associated with Courtship.

MR. JULIAN HUXLEY'S letter in NATURE of December 29 last upon the habits of courtship brings to notice some of the recently ascertained facts. From these he concludes that the conspicuous colours, patterns, and forms made use of in these displays and ceremonies resemble copulatory organs in being subservient to efficiency in securing union of the gametes, and that, therefore, the problem of their evolutionary origin is much simplified and similar to adaptive characters in general.

However, the argument that because they are thus used they are therefore adaptations for the purpose of producing sexual excitement is not justified. It may well be that each animal for display makes use of a bright coloration or conspicuous structure of which the evolutionary origin is governed by some other factor. The dog uses its hind limb to scratch its back, but who would say that back-scratching controls its evolutionary origin?

The fact that polygamy is especially associated with brilliant males, whilst in polyandry females are usually the more highly coloured sex, clearly shows that some other factor governs the evolutionary origin of these secondary sexual differences.

A few other antagonistic facts may be mentioned. In birds it is the rule for the sexes to be similar when they both take part in the rearing of the young, as in the partridge; whereas when the male takes no part, as in ducks, secondary sexual differences are common.

In relatively unpalatable animals the sexes are usually similar, whereas it is in palatable animals that the greatest secondary sexual differences are to be found. Butterflies and birds especially exhibit this distribution.

In predatory animals it is the rule for the sexes to be alike. Instances of differences in coloration between young and adults exactly similar to the secondary sexual differences are widely distributed in birds. Further special difficulties arise in the case of insects, in view of their low visual acuity and poor colour perception which probably precludes the female from ever seeing the colour and pattern of the male. Further, the study of their courtship shows that scent and motion (which tends to conceal colour and pattern) are the means chiefly used to promote sexual excitement.

It is generally agreed that destructive criticism should be accompanied by some alternative explanation, but columns for correspondence do not permit of lengthy expositions. I would, however, offer the explanation that the distribution of secondary sexual colorations is related to the vision of preyer and preyed-upon and the necessity especially to protect the female even at the expense of the male. This thesis is fully expanded in J. C. Mottram's "Controlled Natural Selection" (Longmans, Green and Co., 1914).

J. C. MOTTRAM.

Spontaneous Ignition of Peaty Soils.

I OBSERVE in NATURE of August 25 last (p. 811), which has just reached me, a letter by Mr. E. A. Martin entitled "The Generation of Heath Fires," in which the spontaneous ignition of peaty soils brought about by exposure to the direct rays of the sun is mentioned.

It may be of interest to remark that in this part of the world such examples of ignition of peaty soils are quite common when the soils, in addition to being exposed to the heat of the sun, are brought into a condition of extreme drought.

In certain parts of Cachar and Sylhet, where the conformation of the land is that of a series of rounded hillocks with intervening depressions, the depressions are filled with peaty deposits, often of considerable depth, known locally as "bheels." These bheels have been formed in the usual manner by the continued growth of vegetation in a place where water accumulates, and in the ordinary course of events are always waterlogged.

Many of the bheels have been brought into cultivation and planted with tea, and one of the greatest problems in connection with the cultivation of these areas has been the removal of the enormous amount of water which accumulates in such places during the rainy season, for, in addition to the fact that more than 100 in. of rain may fall on the area in the course of five months, much of the drainage-water from the surrounding hillocks finds its way into the bheels. To this end it has been a common practice to dig an exceedingly wide and deep drain along the lowest part of the bheel, which is generally near the centre, and to drain into this from the edges. In this way the excess water is got rid of in the rainy season, but there has been an attendant disadvantage, in that the bheels are often dried out completely during the dry season. This occurs to such an extent that the crop-yielding period is often unduly shortened, and in many places it is a common practice to block up the mouths of the drains at the end of the rains to prevent excessive drying-out and prolong the period of yield.

Further, during the dry period the bushes are pruned and the land hoed clean, and the area thus loses its protective covering of foliage and weeds.

In such circumstances, in which the dried-out area is fully exposed to the sun's rays, spontaneous combustion in the soil is of common occurrence, and the soil becomes uncomfortably hot to walk on even in heavy boots.

Many acres of tea have been killed out in this way, but no ignition of the bushes occurs above ground, and it is questionable if jungle fires ever originate in this way, for it is only in the exceptional circumstances outlined above that the phenomenon has been found to occur.

Microscope Illumination and Fatigue.

MR. BARNARD's letter in NATURE of December 29 last, p. 566, is unusually dogmatic as a contribution to a scientific discussion. As the title of this correspondence indicates, the original letter was written, not so much to direct attention to a particular method as to a general principle, with the intention of increasing the comfort of workers who have to work long hours at the microscope. It appears that Mr. Barnard has arrived at the same principle independently, but in a case of this nature there is no excuse for withholding from publication a matter which affects the well-being of a large number of workers.

Mr. Barnard condemns the method employed, but perhaps without having given the system described an unprejudiced trial. The ultimate test of any method lies in actual practice. Before publication the resistance-controlled illumination was tested out completely within the limits stated, imposed by the use of light-filters and the nature of the work of this laboratory. Since Mr. Barnard brought up the question of the shift of the dominant radiation—which was irrelevant at the time—further tests have been made with the unscreened light (which is never used for critical work here), and it was found that there was no perceptible loss of resolution or colour differentiation with the lowering of the current. The shift of the dominant is thus not a cause for alarm. A further test showed that to produce equivalent results with neutral filters some eight or ten screens would have to be made, and even then the optimum for every small variation of staining or thickness of section could not be obtained. Such an outfit, with the large amount of experiment and adjustment necessary to get the screens even approximately right, would be quite out of reach of most workers, and could not be conveniently standardised. Further troubles enter with small alterations in the light source due to age and variation of voltage, the general illumination of the laboratory, and, not least, the personal equation.

Shirley Institute, Didsbury, January 4.

Tin Plague and Arctic Relics.

REFERRING to the letter on tin plague in NATURE of December 15 last, it may be of interest to record that in the Museum of Fisheries and Shipping at Hull, among a number of Arctic and Antarctic relics, we have two tins, each about 6 in. in diameter, provided with a thin iron handle on the top soldered on to assist in carrying. These tins, according to the "Guide to the Museum of the Hull Literary and Philosophical Society," published in 1860, and confirmed by that society's minutes, were picked up, among other relics and stores left by Capt. Parry, on Fury Beach in 1825. They were found by Capt. (afterwards Sir John) Ross in 1831, who brought them away with him. Capt. Ross was picked up at sea in a boat by Capt. Humphreys, of the *Isabella*, a whaler of Hull, in 1833, and these relics, among others, were in the boat with him. They were brought to Hull and given to the Literary and Philosophical Society. Eventually this society's collection was handed to the Hull Corporation.

About ten years ago I was curious to know the contents of these two tins, and had them opened; one was found to be full of corned beef in excellent colour and condition, and the other contained pea-soup. Both seemed to be quite fresh, and my attendant sampled them and stated that they were quite good and sweet. He still lives. The soup and the meat are now exhibited in glass jars, and are still in good condition.

My object in mentioning these facts is to show that after being left in the Arctic between 1825–31, and then taken charge of for another two years by Capt. Ross, which means that they were more or less subject to Arctic conditions for eight years, and then having been in Hull for eighty years, the metal does not seem to have deteriorated in any way and it had had no effect upon the contents. Possibly this may be due to the fact that the tins were painted with a thick coat of yellow and green paint respectively, which may have prevented any "plague." If this is the cause, the circumstances may be of value on future expeditions of this character.

The Museum, Hull. T. SHEPPARD.

Inheritance of a Cheek-Mole.

PERHAPS the following case of the inheritance of a mole on the cheek for three generations may be interesting. Records do not go back any further, but, as the representative of the present generation is nineteen, it may be possible to see whether it is continued. The grandfather had a peculiar mole right in the middle of his left cheek. Of his children, two daughters both showed it in almost the same position. The sons did not, but one daughter of one son now has it. There are two boys and two girls in family, but it has appeared only on one girl.

War Against Insects.[1]

By DR. L. O. HOWARD.

COUNT KORZYBSKI, in his recent remarkable book, "The Manhood of Humanity," gives a new definition of man, departing from the purely biological concept, on one hand, and from the mythological-biological-philosophical idea on the other, and concludes that humanity is set apart from other things that exist on this globe by its *time-binding* faculty, power, or capacity. This is another way of saying that man preserves the history of the race and should be able to profit by a knowledge of the past in order to improve the future. It is, indeed, this *time-binding* capacity which is the principal asset of humanity, and this alone would make the human species the dominant type of the vertebrate series. But, biologically speaking, there is another class of animals which, without developing the *time-binding* faculty, has carried the evolution of instinct to an extreme, and has in its turn come to be the dominant type of another great series, the Articulates, or the Arthropods. As Bouvier puts it,

> Man occupies the highest point in the vertebrate scale, for he breaks the chain of instincts and assures the complete expansion of his intelligence. The insects hold the same dominating position in the Articulates where they are the crowning point of instinctive life.

Unlike the Echinoderms and the Molluscs, which have retained their hard coverings or shells, and have therefore progressed more slowly—for, as Bergson says, "The animal which is shut up in a citadel or a coat of mail is condemned to an existence of half sleep"—Vertebrates, culminating in man, have acquired the bodily structure which, guided in man by the equally acquired intelligence, has enabled him to accomplish the marvels which we see in our daily existence. Moreover, the Articulates have in the course of the ages been modified and perfected in their structure and in their biology until their many appendages have become perfect tools adapted in the most complete way to the needs of the species, until their power of existing and of multiplying enormously under the most extraordinary variety of conditions, of subsisting successfully upon an extraordinary variety of food, has become so perfected and their instincts have become so developed that the culminating type, the insects, has become the most powerful rival of the culminating vertebrate type, man.

Now this is not recognised to the full by people in general—it is not realised by the biologists themselves. We appreciate the fact that agriculture suffers enormously, since insects need our farm products and compel us to share with them. We are just beginning to appreciate that directly and indirectly insects cause a tremendous loss of human life through the diseases that they carry. But apart from these two generalisations we do not realise that insects are working against us in a host of ways, sometimes obviously, more often in unseen ways, and that an enormous fight is on our hands.

It is difficult to understand the long-time comparative indifference of the human species to the insect danger, but even during the active lifetime of the speaker there has come a change. Good men, men of sound laboratory training, have found themselves able in increasing numbers, through college and Government support, to devote themselves to the study of insect life with the main end in view of controlling those forms inimical to humanity, and to-day the man in the street realises neither the number of trained men and institutions engaged in this work nor the breadth and importance of their results, not only in the practical affairs of life, but also in the broad field of biological research. The Governments of the different countries are supporting this work in a manner that would have been considered incredible even five and twenty years ago, and this is especially true of the United States and Canada, and scarcely less so of France, Italy, Japan, South Africa, and, at least until four years ago, Russia.

It may be worth while here, however, to point out that certain European countries are combining their studies of agricultural entomology and crop diseases under the term phytopathological studies, or an Epiphyte Service (*Service des Epiphyties*), as in France, and this is undesirable, since it obscures to a certain extent the great issue of insect warfare and divides the great field of economic entomology in a most unfortunate way. Let us hope that the movement will not grow. Let the entomologists co-operate with the pathologists, both plant and animal, wherever there is something to be gained by such co-operation, but let us keep the respective fields entirely clear.

The war against insects has, in fact, become a world-wide movement which is rapidly making an impression in many ways. Take the United States, for example, where investigations in this field are, for the time being, receiving generous Government support. Every State has its corps of expert workers and investigators. The Federal Government employs a force of four hundred trained men and equips and supports more than eighty field laboratories scattered over the whole country at especially advantageous centres for especial investigations. Also there are teachers in the colleges and universities, especially the colleges of agriculture, who are training workers in insect biology and morphology and in applied entomology both agricultural and medical.

[1] Abridged from the presidential address to the American Association for the Advancement of Science delivered on December 27, 1921, at Toronto.

All this means that we are beginning to realise that insects are our most important rivals in Nature, and that we are beginning to develop our defence.

While it is true that we are *beginning* this development, it is equally true that we are only at the start. Looking at it in a broad way, we must go deeply into insect physiology and minute anatomy; we must study and secure a most perfect knowledge of all of the infinite varieties of individual development from the germ cell to the adult form; we must study all of the aspects of insect behaviour and their responses to all sorts of stimuli—their tropisms of all kinds; we must study the tremendous complex of natural control, involving as it does a consideration of meteorology, climatology, botany, plant physiology, and all the operations of animal and vegetable parasitism as they affect the Insecta. We must go down to great big fundamentals.

All this will involve the labours of an army of patient investigators and will occupy very many years—possibly all time to come. But the problem in many of its manifestations is a pressing and immediate one. That is why we are using a chemical means of warfare, by spraying our crops with chemical compounds and fumigating our citrus orchards and mills and warehouses with other chemical compounds, and are developing mechanical means both for utilising these chemical means and for independent action. There is much room for investigation here. We have only a few simple and effective insecticides. Among the inorganic compounds we have the arsenates, the lime and sulphur sprays, and recently the fluorides have been coming in. Of the organic substances we use such plant material as the poisons of hellebore and larkspur, pyrethrum and nicotine; and the cyanides and the petroleum emulsions are also very extensively used. No really synthetic organic substances have come into use. Here is a great field for future work. Some of the after happenings of the war have been the use of the army flame-throwers against the swarms of locusts in the South of France, the experimental use against insects of certain of the war gases, and the use of the aeroplane in reconnaissance in the course of the pink bollworm work along the Rio Grande, in the location of beetle-damaged timber in the forests of the North-west, and even in the insecticidal dusting of dense tree growth in Ohio. The chemists and the entomologists, working co-operatively, have many valuable discoveries yet to make, and they will surely come.

All this sort of work goes for immediate relief. Our studies of natural control follow next. It is fortunately true that there are thousands upon thousands of species of insects which live at the expense of those that are inimical to man and destroy them in vast numbers; in fact, as a distinguished physicist, in discussing this topic with me, recently said: "If they would quit fighting among themselves they would overwhelm the whole vertebrate series." This is, in fact, one of the most important elements in natural control, and is being studied in its many phases by a small but earnest group of workers.

So far, while we have done some striking things in our efforts at biological control, by importing from one country into another the natural enemies of an injurious species which had itself been accidentally introduced, and while we have in some cases secured relief by variations in farm practice or in farm management based upon an intimate knowledge of the biology of certain crop pests, we are only touching the border of the possibilities of natural control. For an understanding of these possibilities we must await the prosecution of long studies.

Let us summarise. Few people realise the critical situation which exists at the present time. Men and nations have always struggled among themselves. War has seemed to be a necessity growing out of the ambition of the human race. It is too much, perhaps, to hope that the lesson which the world learned in the years 1914 to 1918 will be strong enough to prevent the recurrence of international war; but, at all events, there is a war, not among human beings, but between all humanity and certain forces that are arrayed against it. Man is the dominant type on this terrestrial body; he has overcome most opposing animate forces; he has subdued or turned to his own use nearly all kinds of living creatures. There still remain, however, the bacteria and protozoa that carry disease and the enormous forces of injurious insects which attack him from every point and constitute to-day his greatest rivals in the control of Nature. They threaten his life daily; they shorten his food supplies, both in his crops while they are growing, and in such supplies after they are harvested and stored, in his meat animals, in his comfort, in his clothing, in his habitations, and in countless other ways. In many ways they are better fitted for existence on this earth than he is. They constitute a much older geological type, and it is a type which had persisted for countless years before he made his appearance, and this persistence has been due to characteristics which he does not possess and cannot acquire—rapidity of multiplication, power of concealment, a defensive armour, and many other factors. With all this in view it will be necessary for the human species to bring the great group of insects under control, and to do this will demand the services of skilled biologists—thousands of them. We have ignored the insect group to a certain extent on account of the small size of its members, but their small size is one of the great elements of danger—is one of the great factors of their success in existence and multiplication.

Let all the departments of biology in our universities and colleges consider this plain statement of the situation, and let them begin a concerted movement to train the men who are needed in this defensive and offensive campaign.

What the Public Wants.

A STUDY OF THE AMERICAN MUSEUM OF NATURAL HISTORY.

THE American Museum of Natural History probably stands at the head of those museums which set out to interest and attract the general public. In so doing it obeys the clauses of its Acts of Incorporation, but it obeys also the more imperative law of its continued life: to live, a museum, like everything else, must progress; to progress, it needs sustenance. The American Museum, being neither a Government museum, nor a State museum, nor a municipal museum, has to rely upon private endowment and subscriptions. The annual appropriation of the city is confined to the maintenance of the building, and is inadequate even for that purpose. To instal its exhibits, to send out its expeditions, to pay its staff, and to prosecute those scientific researches for which it is celebrated, the museum must arouse private individuals to that degree of enthusiasm at which they will part with their dollars. The mechanism is the enrolment of such individuals as members of various grades, and so successful is it that no less than 5556 members are now enrolled.

Of the numerous ways in which the museum appeals to this great public, and to the far greater public as yet only on the road to membership, we can mention here a bare selection. The most obvious, and the most characteristically a museum method, is the preparation of popular exhibits. The example set by our own Natural History Museum has here been left far behind. The present report furnishes two illustrations, which we are permitted to reproduce. Fig. 1 shows part of a group of the northern elephant seal, from a colony recently discovered on the island of Guadalupe. A small portion of the new Bryozoa group, which represents two square inches of sea-bottom magnified twenty-five diameters, is depicted on two-thirds that scale in Fig. 2. Groups of this latter kind, based on prolonged studies, and carried out with extreme technical skill, are among the most instructive, as well as the most fascinating, novelties. Then there are the larger series, such as the exhibit of the natural history of (modern civilised) man, projected by the Department of Public Health. We in England have done something in this direction, as witness the exhibits of food, of human parasites, and the biology of water-works at the Natural History Museum, but we have not formulated the conception of man in relation to his whole environment of to-day. Temporary exhibitions are useful as keeping a museum alive and attracting fresh sections of the public. Dr. Lucas, the director, does not favour the expenditure of curatorial energy on these, but when they are installed by outside bodies, as the wireless telephone display or the posters teaching kindness to animals, it is only space that he grudges. During 1920 all this activity in the exhibition galleries attracted

FIG. 1.—California sea-elephant group. By the courtesy of the American Museum of Natural History, New York.

937,265 visits (exclusive of attendance on lectures), which compares favourably with the corresponding totals of 851,483 at the British Museum (Bloomsbury), and 527,701 at the British Museum (Natural History).

This number, however, does not represent half the people reached by the popularising and educational work of the American Museum. Forty-eight societies have been welcome to hold meetings, exhibits, or lectures in the meeting-rooms of the museum during the year. Lectures have been given to school children and adults by a special department of public education co-operating with the City Board of Education. This increases the number of visits by 100,750. This department also carries its lectures to the schools themselves, lends lantern-slides by myriads, and circulates 887 special col-

lections among schools and libraries. The number of pupils reached by this outside work cannot be less than a million.

To this direct appeal of the museum specimens the publications are supplementary. Confining our attention to those of educational character, we find, as elsewhere, guides, handbooks, and leaflets, for use primarily in the museum. But reaching far beyond its walls is the well-known Journal of the museum, now issued as a bi-monthly under the title *Natural History*. A copy of this is received by every member, and additional subscriptions amount to 1,570 dollars. The circulation may therefore be taken as well over 6000. Besides its own publications, the American Museum avails itself of the newspaper Press, and by the steady contribution of interesting paragraphs obtains valuable advertisement.

FIG. 2.—Bryozoa group: detail. By the courtesy of the American Museum of Natural History, New York.

We have by no means finished with the ways in which the American Museum increases its membership and otherwise raises its funds. There is, for example, the luxuriously furnished members' room "near the elevator" (Natural History Museum, please note!), and there is the exchange of membership privileges with other museums. But enough has been said to show that all the energy is spent on lines that are productive, and that fact explains how it can be done. In the larger cities of our own country circumstances are not the same. There are limited appropriations for definite purposes, and the governing body, whether municipal or bureaucratic, is not going to take risks with the taxpayers' money. Possibly some of our museum officials rejoice that they do not have to spend their time beating the big drum, and prefer to devote most of their energy and the services of their museums to the advancement of learning rather than to its vulgarisation. Research, they say quite rightly, must come first. None the less, there are features in the educational work of the American Museum which could and should be imitated by more of our Government museums. With them, as with the private corporation of the American Museum, the question reduces itself to one of business. Additional officers must be appointed in charge of these activities, and these officers must be paid. But the public is ready to pay for what it wants, and the case of the guide-lecturers has shown that the Government will respond to intelligently directed and strongly enforced public opinion

Obituary.

DR. EDWARD HOPKINSON, M.P.

THE news of the death of Edward Hopkinson will be received with acute regret by a very wide circle of friends in all branches of science and engineering. Since the General Election of 1918, when Dr. Hopkinson became Member for the Clayton division of Manchester as a Unionist, he was the victim of repeated attacks of influenza, for want of a better name, and was little seen in London; gradually failing, he died on Sunday, January 15, at the age of sixty-two years.

Dr. Hopkinson was the fourth among five sons in a Manchester family, peculiarly united and brilliant, belonging to an aristocracy of industry. His father, John Hopkinson, sometime Mayor of Manchester, was of the firm of Wren and Hopkinson, mechanical engineers, who constructed the machinery for grinding the glass for Chance's lighthouses, a successful demonstration of science and higher industry. His mother, always the true focus of the family, was a Dewhurst of Skipton. The Wills's of Bristol were relatives. The eldest brother, John, the great electrician, whose work was cut short by his untimely death in the Alps, is nobly commemorated in Cambridge; he started on his work as Senior Wrangler. The next brother, Sir Alfred Hopkinson, K.C., of Lincoln College, Oxford, formerly a Member of Parliament for a division of Manchester and for the Cricklade division of Wiltshire, who is still active, had a distinguished legal career, was principal of Owens College, and first vice-chancellor of the University of Manchester. The third son, Charles, a consulting engineer, who died recently, was the trusted counsellor of the whole family. Albert, the youngest brother, of Emmanuel College, Cambridge, became a successful medical practitioner in Manchester, and is now back again in Cambridge as a teacher of anatomy. Of the next generation, Bertram, the lamented head of the Engineering School at Cambridge, lost his life in a flying accident in 1918, and Austin, a successful manufacturer and M.P., is a very vigorous controversialist in social questions. These different distinctions merely represent prominences of characteristics which all shared.

Edward Hopkinson was born in Manchester, and, after completing the course at Owens College, joined Emmanuel College, Cambridge, as scholar,

was ninth Wrangler in 1881, and D.Sc. of London in the same year. He became a fellow of Emmanuel in 1883. He began his fellowship by installing electric light in the hall and chapel for the tercentenary of the college in the following year, and thus anticipated by a few weeks the installation which Lord Kelvin introduced into Peterhouse. He was first with Siemens Brothers, and was resident electrician for the Portrush and Bushmills Railway and the Bessbrook and Newry Railway. He afterwards joined the firm of Mather and Platt when they began electrical work, and ultimately became vice-chairman of the company. He carried out the scheme for the City and South London Railway, and while engaged upon industrial work of that kind he joined his brother John in a paper on dynamo-electric machines in the Transactions of the Royal Society, a paper which speedily became classical. Thereafter he was engaged in electrical and engineering work which brought him into contact with all the active electrical and engineering experts of the country. During the war he was engaged in India on the Indian Industrial Commission. He was president of the Institution of Mechanical Engineers in 1919, but not well enough to deliver the presidential address which he wrote for that body.

Electricity and machinery were not Dr. Hopkinson's only interest; like other members of his family, he was deeply and sanely interested in social questions, and his latest writings are to be found in letters to the *Times* and *Morning Post* on financial matters. Like all the rest of his family, too, he was a keen Alpine climber and member of the Alpine Club, and, like so many climbers, was a remarkably genial host and an ever-welcome guest. He lived in an atmosphere of business, science, and common sense, to which access was easy on account of his family associations; but he contributed his own full share to its maintenance, and the loss of his knowledge and experience is a grave misfortune. He and his brother Charles married sisters, the daughters of John Campbell, of Whiteabbey, near Belfast. His wife survives him. They have one son, formerly an officer in the Army, who is now devoted to anthropology at Cambridge, and a daughter.

NAPIER SHAW.

SIR WILLIAM MATTHEWS, K.C.M.G.

THE civil engineering profession has lost an eminent personality by the decease of Sir William Matthews, who died on January 8 at the age of seventy-eight. From the obscurity of a little Cornish town he rose in the practice of his profession to become the trusted consultant of Government authorities on the most important harbour undertakings in the Empire. His name will long be associated with the annals of harbour construction, and substantial breakwaters in various parts of the world remain as a testimony to his engineering skill. The firm of Coode, Matthews, Fitzmaurice, and Wilson, of which he was until lately the senior surviving partner, have acted as technical advisers to the Admiralty, the Board of Trade, and the Crown agents to the Colonies. At home they were chief engineers for the National Harbour at Dover; abroad they have been consulting engineers for similar undertakings at Gibraltar, Malta, Cyprus, Colombo, Singapore, and Hong-Kong. They are also consultants to several Colonial Governments, the Mersey Conservancy, the Humber Conservancy, and the Tyne Commissioners.

Sir William Matthews was a native of Penzance, where he was born in March, 1844. He served part of his apprenticeship in an engineering works at Hayle, a few miles away. Afterwards he entered the office of his father, who practised as a civil engineer in Penzance. There in 1864 he came under the notice of the late Sir John Coode, who had been called in to advise the Corporation of Penzance. The young assistant was employed to make a survey of the harbour, and acquitted himself so creditably that Sir John took him into his office in London, and ultimately in 1892 into partnership.

The value of Sir William Matthews's services to the Government gained him the C.M.G. in 1901, and the K.C.M.G. in 1906. In 1907 he was elected president of the Institution of Civil Engineers. He became a member of the International Commission on the Suez Canal in 1908, and during the later portion of his career served on a number of committees of public and scientific utility.

COL. CHARLES EDWARD CASSAL, who died on December 22 last, in his sixty-fourth year, was public analyst for the Metropolitan Borough of Battersea, the Royal Borough of Kensington, the Parts of Holland and Kesteven (Lincs), and Chipping Wycombe (Bucks), and joint public analyst for the City of Westminster. He was educated at University College School, and received his professional training at University College, London, where he was demonstrator in the department of hygiene and public health from 1879 to 1888. He was a fluent and forcible speaker, and, having qualified, by examination, for the fellowship of the Institute of Chemistry, he took a prominent part in the discussions relating to the interests of his profession, particularly those of public analysts and official agricultural analysts. Col. Cassal served on the council for six periods of three years each, and as a censor for one year. He frequently accompanied deputations from the institute to Government departments. For fifteen years he was editor of the *British Food Journal*, to which, as well as to other journals, he contributed many articles on the chemistry of food and drugs, on water supplies, and on sewage treatment and disposal.

WE regret to have to record the death of MR. B. P. LASCELLES, who was a science master at Harrow from 1885 to 1901. His great success as a teacher rested on his unbounded interest in everything which appealed to him. It was not enough for him to know about dyes; he made them and coloured his own ties to his fancy! That was in the early days of the synthetic industry. Such

interest is contagious, and so he firmly established the Harrow Scientific Society, as he had helped to found the Junior Scientific Society at Oxford. Though a chemist by training—he was a fellow of the Chemical Society—his activities were at least as wide as those of the British Association, of which he was a keen supporter. His knowledge of palæontology and of archæology was deep. Few indeed were the branches of learning along which he could not guide a young inquirer, so he fulfilled perfectly the offices of librarian and curator of the school museum. The municipal life of his adopted town and county owe much to Mr. Lascelles, whose many friends will ever remember his genial personality with gratitude.

PROF. W. FOORD-KELCEY, professor of mathematics at the Royal Military Academy, Woolwich, since 1903, died on January 3 at the age of sixty-seven. He was a scholar of Exeter College, Oxford, and obtained a First Class in the Final Mathematical School in 1877. He joined the Royal Military Academy as instructor in mathematics in 1878; later he was called to the Bar, and for a time combined legal work with teaching, but eventually gave up the former. Altogether, Prof. Foord-Kelcey was at the Academy for forty-three and a half years, and nearly all serving gunner and sapper officers knew him. He was a man of great ability with brain, hand, and eye, being a first-rate practical mechanic. He had a wide knowledge of mechanism, and retained his interest in the teaching of mechanics to the last. He was due to retire in the summer of this year, and in him the Royal Military Academy has lost a great personality.

FATHER GIUSEPPE LAIS, S.J., whose death in Rome was recently announced, was born in Rome in 1845. He was the author of a very long series of papers dealing with meteorology, both mediæval and modern, solar eclipses, comets and meteors, and astronomical photography. He published some little-known meteorological records of the sixteenth and seventeenth centuries. He took a deep interest in the astrographic chart, and published researches on the best methods of measuring and developing the plates. As vice-director of the Vatican Observatory since 1903 he has had a large share in taking the plates of the zone allotted to that observatory. He was also interested in the question of calendar reform, publishing papers on this subject in 1892 and 1901. Father Lais was for many years vice-secretary of the Accademia dei Nuovi Lincei, Rome.

WE regret to announce the death on January 15, in his ninetieth year, of SIR JOHN KIRK, G.C.M.G., K.C.B., F.R.S., chief officer and naturalist of Livingstone's expedition to the Zambezi in 1858–63, during which he made large collections and many observations of great scientific value. He was the author of numerous contributions to the botany, zoology, and geography of Eastern tropical Africa.

WE regret to see the announcement of the death on January 8, at eighty-six years of age, of PROF. J. H. COTTERILL, F.R.S., formerly professor of applied mechanics, Royal Naval College, Greenwich.

Notes.

THE gold medal of the Royal Astronomical Society has been awarded to Dr. J. H. Jeans for his contributions to theories of cosmogony.

M. RAYMOND POINCARÉ, who has succeeded M. Briand as Prime Minister of France, held that office in the years 1911–13, and was President of the French Republic in 1913–20. He is a brother of M. Lucien Poincaré, the distinguished official head of the University of Paris, who died nearly two years ago, and a cousin of the great mathematician and philosopher, Prof. Henri Poincaré, who died in 1912. In 1914 M. Poincaré was elected Lord Rector of the University of Glasgow, and in November, 1919, he delivered an inspiring address on Franco-Scottish unity to an assembly of four thousand students and other members and friends of the University.

THE Strangers' Hall, Norwich, an interesting old city merchant's house, with groined undercroft, fifteenth-century banqueting hall, and other panelled rooms of later date, has been offered by its owner, Mr. Leonard G. Bolingbroke, to the Corporation of Norwich for the purpose of an English Folk and Historical Museum, in conjunction with the Norwich Castle Museum. Mr. Bolingbroke has also offered his collection of old domestic appliances and other "bygones" illustrative of the various phases of a middle-class Englishman's home during the last four or five centuries, which will find a fitting environment in the various rooms of the house. While the aim of the museum will be historical rather than scientific, there will be found many exhibits of interest to students of the early history and development of such subjects as the production of light and fire, domestic cookery, and other kindred objects.

THE annual meeting of the Institute of Metals will be held in London on March 8–9, when ten important papers are to be presented for discussion. The annual May lecture will be delivered on May 3 by Sir Ernest Rutherford on "The Relation of the Elements." The autumn meeting will be held at Swansea on September 20–22. A large gathering is expected in this important metallurgical centre, and the Mayor and corporation have extended a very hearty invitation to members of the institute. Last year the membership of the institute increased from 1298 to 1410—a record year's growth. Such an increase, occuring during a year of great trade depression, indicates that makers and users of non-ferrous metals and alloys are on the alert to take advantage of the

scientific information obtainable through association with the institute that exists to foster their interests. It is largely through the adoption of more scientific methods of manufacture that the British manufacturer will be able successfully to meet foreign competition, and it is just here that invaluable service is being rendered by our scientific institutions.

THE officers of the Ramsay Memorial Fund announce that the Dean and Chapter of Westminster have consented that a tablet containing a medallion portrait of Sir William Ramsay should be placed in Westminster Abbey in the place immediately below that occupied by the Hooker tablet. The tablet is being executed by Mr. Charles Hartwell, A.R.A. It is anticipated that the unveiling will take place in October next. An announcement will be made on the subject in due course. At the request of the Ramsay Memorial Committee a commemorative medal of the late Sir William Ramsay has been executed by the distinguished French sculptor, M. Louis Bottée. The medals will be struck shortly in London when it is known approximately how many will be required.

ON January 2 occurred the centenary of the birth of Rudolf Julius Emmanuel Clausius, the distinguished mathematical physicist and the predecessor of Hertz in the chair of natural philosophy at Bonn. The son of a pastor and schoolmaster, Clausius was born at Koslin, in Pomerania, and after attending the gymnasium at Stettin, spent four years at Berlin, where he studied under Dirichlet, Steiner, Dove, and Magnus. Before going to Bonn he held appointments at the Royal Artillery School, Berlin, Zürich Polytechnic, and Würzburg University. Recognised as one of the founders of the science of thermo-dynamics, it was in his memoir to the Berlin Academy of Sciences in 1850 that he re-stated Carnot's principle in its correct form. To him is also due the conception of entropy. His chief work, "Die Mechanische Wärmetheorie," appeared in 1867. The kinetic theory of gases and the theory of electrolysis also owed much to his labours. Among his honours was that of the receipt of the Copley medal, while the Institution of Civil Engineers made him an honorary member. He was called to Bonn in 1869, served as Rector of the University during 1884–85, and died there on August 24, 1888.

IN his presidential address to the American Association for the Advancement of Science, delivered in December last at Toronto, Dr. L. O. Howard made some interesting remarks on the ages of presidents of the British and American Associations. The average age of the presidents of the British Association during the period 1895–1920 was sixty-one years and eleven months, and of those of the American Association sixty-one years and five months. The youngest president of the British Association during that period was fifty-three years of age, and Sir A. W. Rucker (1901), Sir J. J. Thomson (1909), and Prof. W. Bateson (1914) were each fifty-three years of age when serving as president. The oldest was Prof. T. G. Bonney (1910), whose address was delivered at the age of seventy-seven. The youngest of the American presidents were Minot and Richards, whose addresses were delivered at the age of fifty; and the oldest was Eliot, whose Philadelphia address was delivered when he was seventy-nine years of age. "We may safely assume," remarks Dr. Howard, "that the usefulness of the man past middle age is granted, and that, while he may not have the illuminative bursts of inventive or speculative genius which come to the younger man, he is better able to make the broad generalisations based upon accumulated experience—in other words, to prepare an appropriate presidential address as president of the British or the American Association for the Advancement of Science."

AT the Institution of Electrical Engineers on January 12 there was an interesting exhibition of instructive American cinematograph films. The first film, which was exhibited by Dr. Garrard, showed tests of high-tension switchgear. The experiments with switches were made with currents of the order of 100,000 amperes, the object being to find out how the apparatus withstood the enormous mechanical stresses set up by these very large currents. The films were first shown at the ordinary speed; they were then shown at a reduced speed, so that the various effects produced could be followed. The tests made on current and potential transformers showed clearly the types which withstood the stresses best. In some cases switching on the power produced effects similar to those produced by a high-explosive bomb. A noteworthy educational film called "The Audion" was also exhibited. It explained very clearly the operations which are believed to take place between the transmitter and the receiver in radio-telegraphy. The electrons are shown in active motion round the filament of a thermionic tube, and the artist shows by means of them the valve action of the tube. Similarly, the amplifying action of the grid is explained by the motions of the electrons. The currents in the antenna and the waves leaving it were also shown in motion, the whole producing a very lively representation of what takes place. The films were made by the Western Electric Co. of America for the instruction of their employees. Another film showed the building up of a telephone, all the various parts of it slowly and deliberately getting into their proper places apparently by their own agency.

THE annual meeting of the Mathematical Association was held on January 2–3, and Sir T. L. Heath was elected president as successor to the Rev. Canon J. M. Wilson. Papers were read by Sir George Greenhill on "Mathematics and Artillery: Before and After the War: A Review of the Outlook: Then and Now," and on "The Structure of the Atom" by Dr. J. W. Nicholson. Prof. C. Godfrey delivered an address on the importance of the introduction of vectors in the work of the secondary school—a subject on which several writers in the *Mathematical Gazette*

have written strongly of late. Miss F. A. Yeldham's paper on "The Dalton Plan and the Teaching of Mathematics" aroused considerable interest; an animated discussion followed, with many inquiries as to the details of her experiences of the plan as at work in the Streatham schools. Prof. G. H. Hardy gave a most interesting address on the life and work of that Indian genius, the late Srinivasa Ramanujan, which was full of personal recollections. He set forth with consummate skill the nature of Ramanujan's researches, his successes, and his failures. He also made an eloquent appeal for a wide extension of education in India, assuring his audience that with such opportunities for the great peninsula as we enjoy here in the West there would soon be an Indian school of mathematics at least equal to anything that can be shown in Europe or America. Incidentally he condemned the folly of those who have decried the Germans as lacking in originality. The next paper was by Mr. A. Dakin, who pleaded with much effect that pure and applied mathematics should be taught and developed *pari passu* in boys' secondary schools. The meeting was brought to a close with a discussion opened by the Rev. E. M. Radford on the best ways of keeping teachers of mathematics in touch with modern developments and methods—a most important problem, and one for which a solution must be found in the near future.

In an interesting paper contributed to the Journal of the Royal Anthropological Institute (vol. 51, part 1) Prof. F. G. Parsons arrives at conclusions, which may be quoted in his own words, in connection with the Long Barrow race, and its relationship to the modern inhabitants of London. He believes that "the shape of the skull is the result of vital or physiological forces, some of which we grasp feebly, and others which we do not understand at all as yet, acting on it for a very long time; but that shape, once established, is very permanent, and most of its characteristics remain for thousands of years after the race bearing them has changed its habitat. Even when the race has been practically bred out by competing races, better adapted to the changed conditions, all the old characters reappear from time to time, sometimes singly, but occasionally all together." For example, the skull of Jonathan Wild reproduces all the characters of the Long Barrow race. "Finally, I must admit that the skull of the modern twentieth-century Londoner has changed from that of the eighteenth, but it is in the direction of increased breadth and shortness, and the change is due, I believe, to admixture with the Central European or Alpine race, which in the last two centuries has been pouring into this country in ever-increasing quantities."

As stated in NATURE of December 30, 1920 (vol. 106, p. 583), the first Pan-Pacific Scientific Conference resolved that fuller knowledge of the history and culture of the Polynesian race was essential to the solution of the ethnographic problems of the Pacific. The Report of the Director of the Bishop Museum, Honolulu, for 1920, just received, informs us that Mr. Bayard Dominick, of New York, is financing an expedition for the study of Polynesian origin and migration. This is organised by the Bishop Museum in conjunction with authorities from countries bordering on the Pacific. During 1920–21 parties have been stationed on the Marquesas, Austral, Tongan, and Hawaiian Islands to establish standards of physical form, material culture, traditions, and language of the Polynesians. During 1921–22 a boat with a scientific staff is making observations in selected localities along the route Honolulu, Wake, Marshall, Eastern Carolines, Gilbert, Ellice, Samoa, Tonga, Friendly, Cook, and Society Islands, returning to Honolulu *via* Tongareva, Malden, Christmas, and Fanning Islands. The Bishop Museum acts as permanent representative of the first conference. Its director, Prof. H. E. Gregory, is chairman of a committee to arrange for future conferences, and associated with him are E. C. Andrews (Australia), C. M. Fraser (Canada), F. Omori (Japan), Charles Chilton (New Zealand), and T. Wayland Vaughan (United States).

THE latest issue of the *Archiv für Kriminologie* (Bd. 72, Heft 3–4) contains an important article by Prof. W. Ostwald, of Leipzig, entitled "Das System der Kriminologie," in which he attempts a classification of the subject-matter of criminology. He starts from a classification of science as a whole under three main headings: (1) Mathetics, subdivided into logic, mathematics, geometry, and kinematics; (2) energetics, subdivided into mechanics, physics, and chemistry; and (3) biotics, subdivided into physiology, psychology, and sociology. Applying this classification to criminological studies, he arrives at a schedule in which criminology in the more restricted sense falls under sociology, while the contributions of sciences auxiliary to criminology proper, such as criminal anthropology and criminal psychology, fall under the earlier and more general headings. Prof. Ostwald gives an example of the working of his scheme as applied to a large number of titles taken from criminological literature. As an attempt to introduce some sort of order on a logical basis in a subject with a wide scope and a vast literature, this classification will be welcome to students. Its terminology, however, if only for the sake of clearness, needs revision and amplification. As it stands at present the titles of the divisions of the schedule are not sufficiently indicative of their content to be of much practical utility as guides. In addition to Prof. Ostwald's paper, this issue of the *Archiv* contains a number of interesting contributions by prominent criminologists, among the more noteworthy being a long account by J. P. L. Hulst, of Leyden, of a number of cases of necrophilia, an examination by Prof. Allfeld and Prof. von Beling of a proposal put forward by Dr. R. Hindl for the treatment of habitual criminals, and a valuable note by Mr. Arthur Macdonald, of Washington, on the possibility of using police records, particularly records for identification purposes, for the anthropological study of the population.

WE have received the Report of the Bacteriological Section, State Board of Agriculture, U.S.A., for 1920. Much work has been done on the keeping qualities of butters, the decomposition of peat, silage production, bovine infectious abortion, various fermentations, soil and food. For the isolation of the *Bacillus abortus*, the causative organism of infectious abortion, a liver agar medium is recommended with an addition of 1 in 10,000 gentian violet. The medium should have a hydrogen-ion concentration of between 6·6 and 6·4, and the cultivation should be conducted in a closed chamber, in which 10 per cent. of the air is replaced by carbon dioxide.

An account of the brachyuran crabs collected by the American Museum Congo Expedition has been published recently by Miss Mary J. Rathbun (Bull. Amer. Mus. Nat. Hist., vol. 43, pp. 379–474, 30 plates). The collection contains about 3000 specimens belonging to forty-three species, and the large series has enabled the author to define many of the previously known species with greater accuracy. Three of the four species of Callinectes known to occur on the West African coast are well represented in the collection, and details of their systematic characters are given. The author states that the collection of land crabs (Cardisoma), about 120 specimens, serves to demonstrate that certain differences between the African species, *Cardisoma armatum*, and the American species, *Cardisoma guanhumi*, are constant. The river crabs (Potamonidæ) form the most important part of the collection, and are represented by nine species, four of which are new. Notes on the bionomics of these crabs are added by Mr. H. Lang, leader of the expedition.

THE rodents of North America, prairie dogs, ground squirrels, pocket gophers, jack-rabbits, field mice and rats, are responsible for depredations amounting to 100,000,000*l*. a year to field crops, pasturage, and stored products. Mr. W. B. Bell, in the Year-Book of the United States Department of Agriculture for 1920, gives an account of the damage which they do, and of the measures taken to control or eradicate them. The matter was first taken up by the Biological Survey, which devised means both of prevention and cure. By their field operations and by demonstration plots they were able to convince the farmer and stockman of the efficacy of their measures, and in this way they won their co-operation, as well as financial support from the individual States of North America. The work now comprises thoroughly organised aggressive campaigns in sixteen of the Western States. The two chief methods of control are poisoning by strychnine and organised drives, and the methods of prevention include the erection of rodent-proof fencing and the introduction of rat-proof devices into buildings used for storage purposes. Mr. Bell's account gives a vivid idea of the menace which these rodents are to the food supplies of North America, and the valuable results obtained by organised effort on a comprehensive scale for their control and eradication. The menace is equally serious in this country, and the measures adopted in America deserve the serious consideration of the Government and local authorities here.

WE have received an interesting letter from Mr. J. Anderson, of Sewerby, near Bridlington, stating that one of a fine group of the Chilean tree, *Araucaria imbricata*, at Sewerby House had produced a large number of seeds from which healthy young plants have been raised; he asks if this is an unusual occurrence. Mr. W. J. Bean, Royal Botanic Gardens, Kew, informs us that this is not a rare occurrence, and for many years past trees in various parts of the country have borne fertile seeds. He remembers so long ago as 1906 seeing self-sown young plants at Castle Kennedy, in Wigtownshire, growing beneath the trees from which the seeds had fallen. Similar self-sown seedlings may be seen at Strathfieldsaye, the seat of the Duke of Wellington; and other places where fertile seeds have been developed are Beauport, Tortworth, Castlehill, in North Devon, and Bicton, in South Devon. Mr. Anderson also states that some twenty-five or thirty years ago one of the trees "bled to death" from a scar caused by the breaking away of a branch. This also has been known to happen before. A case is known where a tree died from a running wound made at its base by the scythe of a workman mowing the grass. Mr. Anderson, however, records an interesting fact that we do not remember to have seen noted before: when the roots of the dead tree were being removed the workmen dug up large quantities of resin which had set into hard, amber-like masses. The seeds are eaten by the Araucanos and other Indian tribes in Chile. Mr. H. J. Elwes, who visited the native forests of this tree in 1901–2, states that he has eaten them both roasted and boiled and found them very palatable, with a nutty flavour somewhat like that of almonds.

DEVELOPMENT of the petroleum resources in Alaska has been, as we might have expected from the nature of the country, an extremely slow and somewhat costly matter; the comparative inaccessibility of the oil-bearing territory and the rigorous climatic conditions have combined to retard progress to the point of questioning the justification of a continuance of operations. The first well was brought in at Katalla in 1901, and was followed by a short-lived oil boom, afterwards depressed by the wonderful results of Californian development; since that year forty wells have been drilled in Alaska, thirty-one in the Katalla field and the remainder in other prospects, including the Iniskin Bay and Cold Bay districts; Yakataga, on the Pacific seaboard, and Smith Bay, on the Arctic coast, are mentioned as further areas where indications are good. The total production to date amounts to some 56,000 barrels of crude oil which has been refined and used locally; the oil is of paraffin base, of specific gravity varying from 41° to 45° (Baumé), high in petrol, and with no sulphur content; it is obtained from Tertiary beds the structure of which is at present doubtful. Geological exploration is a matter of great difficulty, and the results set forth in the preliminary report on the country (U.S. Geol.

Surv., Bull. 719) can only be regarded as tentative. It is doubtful whether Alaska will ever take rank as an important producing country, but oil will probably be obtained in sufficient quantity to meet local requirements.

SOUTHPORT CORPORATION has issued its annual report of meteorological observations for the year 1920, the results and discussions being carried out by Mr. Joseph Baxendell, meteorologist to the corporation. The report is circulated by the Air Ministry through the Meteorological Office and by the Corporation of Southport, as was done with the results for the year 1919. For many years these reports have stood out as specimens to show what can be done by corporations in England when there is a desire to aid in the advance of meteorology. The observations for 1920 are admirably treated, but there is rather less discussion of the observations than in some recent years, possibly due to the real lack of sufficient scientific assistants; it is stated in the report that a research computer is greatly needed. Research is going on to establish the trustworthiness of a five-year periodicity for wind direction, temperature, and rain in north-west England, and observations are contributed to the Meteorological Office for the daily, weekly, and monthly weather reports. The mean temperature of the complete year was 49·2° F., or 1° above the forty-five years' average. The total duration of sunshine in 1920 was 1277 hours, or 279 hours less than a twenty years' local average, and the smallest annual value yet recorded at Southport. North-westerly winds were deficient throughout the year, the deficiency amounting to little less than double the largest previous annual deficiency from that direction. The dominant feature of the year was the exceptional prevalence of winds from the southern half of the compass. The total rainfall for the year was 34·08 in., which is 1·24 in. above the normal. Observations of diurnal variation of wind direction and velocity, air temperature, and sunshine are of especial interest; as are also the observations of atmospheric pollution.

WIND observations in various Finnish lightships taken between 1914 and 1920 (Ström- och Vindobservationer vid Fyrskeppen) have been published by Dr. G. Granqvist in *Havsforsknings Institutets*, Skrift No. 10, 1921. The observations are from fourteen lightships in the Gulfs of Bothnia and Finland and one in Lake Ladoga. Most of them ceased late in 1914 and throughout the years 1915 to 1918, but the series is fairly complete in 1919 and 1920. The data, which were taken three times daily, are given in detail.

SEVERAL useful pamphlets on map projections have been issued by the Department of Commerce of the United States Coast and Geodetic Survey. A study of map projection in general (Special Publication No. 60) treats in a few pages with numerous illustrations of the fundamental ideas underlying the subject. A larger work is "Elements of Map Projection," by C. H. Deetz and O. S. Adams (Special Publication No. 68), which deals both with the theoretical side of the subject and the practical details of the construction of some of the most important projections. It is copiously illustrated with maps and diagrams and supplied with tables for the construction of Mercator's projection. At the low price of 50 cents it should find ready acceptance in this country. The third pamphlet (No. 67) deals with latitude developments connected with geodesy and cartography, and includes tables for the Lambert equal-area meridional projection.

THE paper read by Sir Vincent Raven before the North-East Coast Institution of Engineers and Shipbuilders on December 16 last is noteworthy, as it makes out a strong case in favour of electric traction on railways. The author is the chief mechanical engineer to the North-Eastern Railway Co., which is about to electrify 250 miles of its main-line system. It is well known that the steam locomotive engine has only half the economy of the steam stationary engine of the same size owing to the great difference in the economy of the boilers in the two cases. The question to be considered, therefore, is whether the great economy that could be effected by generating power on a large scale in a fixed station would be counterbalanced by the unavoidable losses in transmission and the interest on the capital cost of the transmission lines. The author quotes data which prove that electric traction is in nearly every case the more economical. As the North-Eastern Railway Co. intend to purchase their electricity from the supply companies operating in the district, a probable result will be the reduction in the price of electricity to ordinary consumers. This happened in 1904 when the Tyneside passenger lines were electrified.

IN a recent catalogue of the Snook apparatus by Messrs. Newton and Wright, Ltd., we find useful descriptions of two models of this well-known and trustworthy transformer; the Standard model is intended for radiographic work only, the Universal for all purposes, including deep therapy. This latter model is insulated with oil, and is also suitable for X-ray tests upon metals and for the many industrial purposes for which X-rays are being used. A brief description of a new time switch is given; this is based entirely on mechanical principles, and should form a useful addition to a radiographic outfit, for it has a working range of automatic action from 8 seconds to 1/30th of a second.

MESSRS. J. WOOLLEY, SONS AND CO., LTD., of 76 Deansgate, Manchester, have issued their annual pocket-book, "The Scientist's Reference Book and Diary for 1922," price 3*s*. 6*d*. In addition to the usual information given in diaries, there are brief particulars of the more important scientific societies and departments and numerous tables of physical and chemical constants which make the little volume extremely useful to teachers of science and other scientific workers.

DR. A. S. RUSSELL has written, for publication by Mr. John Murray, "The Chemistry of the Radio-elements." The work is intended to describe in a simple and concise form the main facts concerning

the chemical properties of the radio-elements and the bearing of this knowledge upon inorganic chemistry and theories of the structure of the atom. Among the topics dealt with are the relation of the radio-elements to the periodic system of classification, the properties of isotopes, the separation and purification of individual elements, and the analytical chemistry of uranium, thorium, and radium.

THE spring announcements of the Cambridge University Press contain several items of scientific interest, among which is the first volume, bearing the sub-title Foundations, of a forthcoming book by Prof. H. F. Baker entitled "Principles of Geometry." We learn from the preface that the work seeks to introduce the reader to those parts of geometry which precede the theory of higher plane curves and of irrational surfaces. Vol. 1 is devoted to the indispensable logical preliminaries. It assumes only those relations of position for points, lines, and planes which, furnished with a pencil, a ruler, some rods, and some string, a student may learn by drawing diagrams and making models. It seeks to set these relations in an ordered framework of deduction, gradually rendered comprehensive and precise enough to include all the later theory; to this end it puts aside, at first, most of those intricate details which make up the burden of what is generally called elementary geometry. Later volumes will deal, on the basis of the results obtained in this volume, with conics (and circles), with quadric surfaces and cubic curves in space, and with cubic surfaces and certain quartic surfaces.

Our Astronomical Column.

THE ORIGIN OF BINARY STARS.—Dr. J. H. Jeans discusses this question in the January issue of *Scientia*. He notes that binaries are of such frequent occurrence (practically half the stars) that we cannot regard them as freaks or abnormalities, but must seek for some explanation of very wide applicability. He considers three possible origins: (1) through fission of a single mass; (2) formation of adjacent nuclei in the original nebula, sufficiently close to each other to be held together gravitationally; and (3) capture, arising from the appulse of two stars originally independent. The last could lead to capture only if a resisting medium were present; moreover, there would be far too few close appulses to explain any appreciable fraction of the existing binaries. Dr. Jeans estimates that in a universe of a thousand million stars there would be ten thousand captures in a thousand million years. The first suggestion is shown to be possible only when a certain density of the rotating star has been attained (probably about that of the stars of B type). It is shown that this explanation accords well with the observed phenomena in the case of spectroscopic binaries, notably the low eccentricity of their orbits. Russell and others, however, have shown that the latus rectum of the orbit cannot increase very greatly, save under the action of considerable external forces, which are certainly not present now, and could only have been present in the past if the interstellar distances were then much smaller.

A test of the fission theory is afforded by triple systems, which generally consist of a close pair with a distant companion. Prof. Russell showed that the density of the central star would be at least 380 times greater at the second fission than at the first, which leads to such an improbable figure as to throw very grave doubts on the fission theory in the case of the wide pairs. Hence the second suggestion is taken to be by far the most probable explanation of the latter pairs. It must, however, be considered to indicate the *how* rather than the *why*; for the question remains why there should be so marked a tendency for nebular condensations to occur in pairs.

Dr. Jeans notes that star groups with common motion, such as the Taurus and Ursa Major clusters, can be most readily explained as arising from adjacent condensations in a primitive nebula; in these cases, however, the mutual distances were so great that the stars were outside each other's field of gravitational control.

THE ORBIT OF CASTOR.—Dr. W. Doberck gives in the centenary number of *Astron. Nachr.* an explanation of Villarceau's method of computing double-star orbits, which is analogous to Laplace's method for planetary orbits. He illustrates it by revising the orbit of Castor from the following four positions: 1719·84, 357·0° (4·82″); 1832·0, 259·0°, 4·61″; 1880·0, 234·5°, 5·63″; 1920·0, 216·0°, 5·03″. The first distance was not observed, but calculated. The author utilises his earlier orbit to shorten the approximations, and obtains the following orbit: ☊ 222° 7′, λ 67° 19′, γ 116° 6′, e 0·2875, P 477·5 years, T 1960·51, a 6·573″.

Predicted places, 1930·0, 210·4°, 4·58″; 1940·0, 203·0°, 3·98″. Owing to the approach to periastron the motion is accelerating It should be possible to obtain the relative masses of the components before very long; this is desirable as a check on the result suggested by the spectroscopic observations, which give the faint star six times the mass of the bright one.

SPECTRUM OF α CYGNI.—This spectrum is interesting from its relationship to the spectra of novæ. Its classification is A 2 (peculiar), and Dr. W. H. Wright has made a special study of the ultra-violet region, which is described in Lick Obs. Bull. No. 332. A spectrograph with two quartz prisms was attached to the Crossley reflector, and three photographs taken on June 11, 1921, two of them being on films which were bent to correspond with the curvature of the field. The limiting wave-lengths are 3245 to 4102, and 184 lines are recorded in the table, most of them being identified with known metallic lines, but they are unusually sharp and narrow compared with other A spectra. The hydrogen Balmer series is complete from Hδ to Hω. Dr. Wright states that the resemblance to the spectra of novæ is still more striking in the ultra-violet than in the visual region. A curve is given of the spectral intensity on the photographs: it falls very steeply between 3750 and 3650, then slowly and uniformly to 3245. The paper also contains some measurements of the red end of the α Cygni spectrum taken on stained plates. It is incidentally proved that some lines announced in this region by Dr. Waterman from photographs with a grating spectrograph really belonged to the blue region of the overlapping third-order spectrum.

Congress of Philosophy in Paris.

THIS congress, which was held in Paris on December 27–31 last, was organised by the Société française de Philosophie. It was not international in the same sense as the series of conferences interrupted by the war, but consisted of a special session of the French society, in which British, American, Italian, and Belgian societies were invited to take part by sending delegates. The British delegates were members of the Aristotelian Society, and included Prof. Wildon Carr, Miss H. D. Oakeley and Dr. Dorothy Wrinch, of the University of London, Prof. J. A. Smith, Mr. W. D. Ross, and Dr. F. C. S. Schiller, of the University of Oxford, Prof. W. R. Sorley, of the University of Cambridge, and Prof. Hoernlé, of the University of Durham.

The session was admirably organised under four sections. The first, devoted to logic and methodology, was presided over by M. Paul Painlevé; the second, devoted to metaphysics and psychology, by M. Henri Bergson; the third, which dealt with the history of philosophy, was under the presidency of Prof. Levy Bruhl; and the fourth section, dealing with social and moral philosophy, was organised by Prof. Bouglé. The mornings were occupied with sectional meetings; in addition, each section arranged one general afternoon meeting. Receptions in honour of the delegates were given by the president of the Société française and by the Rector of the Sorbonne, and the Société française de Philosophie also entertained all the members of the congress to dinner at the Club de la Renaissance.

Recent Developments of Relativity Theory.

In Section I. two subjects of scientific interest were discussed, viz. the theory of relativity and the theory of probability. The discussion of relativity, under the chairmanship of the president of the Société française de Philosophie, was opened by Dr. Dorothy Wrinch, who gave an account of the developments of the theory of relativity due to Weyl and Eddington. She explained how the electromagnetic-force tensor has been identified with a quite specific function of definite significance, in virtue of the fact that the electromagnetic force satisfies the usual Maxwellian equations, by means of an extension of the geometrical system dealt with by Einstein. Dr. Wrinch pointed out that the method of achieving this result was logically similar to the method used by Einstein in his identification of the energy tensor, covering energy, momentum, and stress in a field, with a certain function in his generalised geometry, and, indeed, the function used by Eddington in his further generalisations (Proc. Roy. Soc., 1921). Dr. Wrinch then referred to the existence of the new tensor discovered by Eddington (*ibid.*), and also to the fact that, although it is a development of the ordinary $^*G_{\mu\nu}$ tensor (in the sense that the $^*G_{\mu\nu}$ tensor is an abbreviated summary of it), its physical significance is very uncertain at present. The important logical procedure adopted by Eddington in the introduction of the axiom of the comparability of proximate relations was then made clear.

Prof. Langevin, who followed, gave an account of the development of the theory of relativity from its origin in the experiment of Michelson and Morley to its ramifications at the present day. He laid particular stress on the parallelism which has occurred in the development of geometry and physics, and he contrasted at some length the very different characteristics of these two parts of the theory of relativity. Prof. Langevin then gave an account of the curious manner in which non-Euclidean geometry has been developed from the Euclidean geometry of the last century, and he described the successive generalisations due to Weyl and Eddington. In the course of his exposition of Eddington's results Prof. Langevin then pointed out the manner in which geometry seems now to have gone ahead of physics, in that the geometrical function referred to above has not as yet been identified with any physical idea.

M. Paul Painlevé, who was the next speaker, brought forward certain objections to the theory of relativity which he had already indicated in two communications to the Paris Academy of Sciences in October and November last. He discussed in particular the admissible forms of the interval length ds, and pointed out the fact that various generalised functions $f(r)$ might be substituted for r in the coefficients of the squared differentials in the usual formula for the square of this interval length. All these forms indifferently satisfy the conditions, giving (*e.g.*) the same resulting motion of the perihelion of Mercury, but differing, on the other hand, in regard to the effect of solar gravitation on light traversing the sun's field. M. Painlevé laid great stress on this multiplicity of possible forms, and criticised the theory of Einstein on the ground of the multiplicity of possible forms in this particular formula and in other formulæ introduced at later stages.

A further objection was brought against the theory on the ground that no dynamical system can be constructed unless a privileged set of axes exists. Prof. Langevin, afterwards dealing with this point and with some of the paradoxes arising from it, and also from certain other postulates, pointed out that all theories allow the existence of a privileged set of axes in the neighbourhood of each point, but that no one set is necessarily applicable to the whole universe. A spirited discussion between the above-mentioned speakers followed, which dealt chiefly with certain of the more striking paradoxes to which the theory appears inevitably to lead.

The Theory of Probability.

Another meeting of Section I. of the congress—on this occasion a purely sectional meeting—discussed the modern developments of the theory of probability. The chair was taken by M. Hadamard, in the regretted absence of M. Emil Borel on account of illness. In his paper on "Les Axiomes du Calcul des Probabilités," M. Paul Lévy made public some important results which he has recently obtained by the application of the analytical ideas used by Lebesgue in his work on the theory of functions to F(x), the function representing the probability of an event x. The starting point of his theory is the fact that this function F(x) is necessarily a monotonic increasing bounded function of x. M. Lévy introduces $\phi(z)$, a *fonction caractéristique* of the probability, by refining it in terms of a Stieltje's integral,

$$\phi(z)=\int_{-\infty}^{+\infty} e^{izx}d\mathrm{F}(x).$$

This function he finds to be sufficient to determine F(x), and to be of fundamental importance in the later development of the leading ideas in a strict mathematical form. The paper raised many new points of

remarkable interest. For example, it pointed out the possibility of applying many of the most far-reaching results obtained by the modern school of analysts to this function $F(x)$ by means of a careful consideration of the assumptions which can plausibly be made concerning the characteristic properties of this function $F(x)$.

In the discussion which followed the reading of this paper, the "frequency" view of probability, according to which the probability of an event is a property definable in mathematical terms, was supported by M. Carvallo; but the contradictory view, which is, of course, the view of the majority of recent writers on the subject in England, was maintained in interesting speeches from M. Hadamard, Prof. Langevin, and others.

Geographical Outlooks.

THE Geographical Association held its annual meeting at Birkbeck College, London, on January 5 and 6. Lord Robert Cecil, as president, spoke on "Geography and Peace." If the Washington Conference was more efficient for peace than the League of Nations Council, this was partly because the latter had serious geographic constitutional defects, such as the absence of German, Russian, and United States representatives. Self-determination was easy to enunciate but most difficult to apply, because geographic conditions had resulted in extraordinary intermingling of peoples who, with inexplicable perversity, declined to live in watertight compartments. Racial and linguistic complexity is not, however, an impassable barrier to governmental unity, as Switzerland, with its three component peoples differing in history, language, and religion, indubitably proves. The Silesian decision was full of geographic interest. For purposes of tariffs, passports, and transportation the political boundary is ignored, and this may be a first experiment towards serious future modification of our State system.

Mrs. Ormsby (London School of Economics) from long-continued researches gave a demonstration lecture showing remarkable connections between original contours and drainage of London and Westminster and their present configuration. Her detailed contour maps are of great scientific interest, and should be published. Sir Halford Mackinder suggested that London originated as the port of St. Albans. Mr. R. L. Thompson (Rugby School), pleading for the better teaching of both history and geography, emphasised the need for superseding the narrowness of the personal and local points of view. We should envisage the weaving of the pattern of life linked through the ages by history and through space by geography. Sir Halford Mackinder spoke on problems of the Pacific. He asked for geographic imagination of the Pacific as a unity instead of the too prevalent view of it as a distant fringe of the European peoples. The Washington Conference had not laid down the limits of the Pacific, and this might be a serious omission, since such populous and prosperous islands as Java lie in the doubtful zone. The Pacific coastal fringes must become incalculably important because of their coal, mineral, and agricultural possibilities.

Dr. Fleure, hon. secretary of the association, lecturing to a joint meeting of historians and geographers, urged that subject-barriers in education should be diminished and that historians and geographers should co-operate to attain broader truth about human evolution. The long, bitter Russian winter so lowers human efficiency that continuously efficient popular criticism of government is impossible, and traditional routine is therefore important. In France the Roman South and the Paris basin differ historically in language, law, architecture, and economics. The boundary between them is a zone, not a line. Our political system needs re-adjustment by recognition of the zonal characters of frontiers. The maps of cities are full of clues for interpreting their life, and, when compared, illustrate remarkably the medieval spread of civic development from the Paris basin along the European plain. Mapping of prehistoric facts is another geographic study which will help to trace back the lineage of human institutions beyond the age of documents.

Miss L. Winchester (Liverpool University) discussed climatic variations in Palestine and factors of the serious summer drought which make storage for water from the winter rains an outstanding problem.

Dr. Hogarth lectured, with many original slides, on Hejaz as a central section of the age-long trade route between Syria and Yemen, with Mecca and Medina as stations on either side of an immense and high bluff of barren volcanic rock. The growth of Muhammadan life and pilgrimage on this basis was implicitly suggested, and its influence on the country was worked out to the practical conclusion that Hejaz could scarcely become a commanding political unit.

The outstanding features of the annual business meeting were the remarkable enthusiasm for geography shown by the fact that eleven hundred new members had joined the association during 1921, and the resolution sent to the Board of Education urging that, while fully recognising the enormous service which the system of advanced courses had rendered in raising the standard of secondary education, the Geographical Association felt that changed conditions emphasise the need for much greater freedom of teaching and grouping of subjects.

The Bow in Homeric Times.

THE Huxley memorial lecture of the Royal Anthropological Institute was delivered on November 29 by Mr. Henry Balfour, the title of the lecture being "The Archer's Bow in the Homeric Poems."

Mr. Balfour said that the principal passages in the Homeric texts relating to the archer's bow were: (1) the description of the bow of Pandarus (*Iliad*, IV.); (2) the account of the bow of Odysseus (*Odyssey*, XXI.). Both these bows were described merely as made of horn, but it was impossible to believe that *horn alone* was used in making so powerful a bow as that of Odysseus The bow of the Lycian Pandarus was made, according to the poet, from the horns of a single wild goat, but, on zoological grounds, this description could be shown to be inadequate, as such horns, if unaided, would not furnish material for making a practicable bow. It was suggested that either the horns of the Armenian wild sheep, or,

more probably, those of the water-buffalo, were used for both the bows referred to, and that even these would have required to be reinforced with a powerful "backing" of sinews to render them strong and efficient. Zoological, archæological, and ethnological evidence was adduced to show that in all probability the Homeric bows were true composite bows, built up with staves of wood and horn, and "backed" with sinews, after the fashion prevailing among the more skilled Asiatic bow-makers of later times. A study of Asiatic and Turkish composite bows showed that in all cases the sinew "backing" was protected by a sheathing of thin bark or leather, which concealed this part of the structure; while in many instances the horn forming the "ventral" surface was left uncovered and exposed to view. This fact may account for horn alone being referred to by Homer, since only this element in the structure was visible.

The following facts supported the theory of composite, sinew-backed construction:—

(1) The bows referred to in Greek texts are very frequently described as *reflexed* (παλίντονα) in the *unstrung* state. This is a special feature of composite bows.

(2) The extreme curvature imposed upon the bow of Pandarus when fully drawn (κυκλοτερὲς τόξον ἔτεινεν).

(3) The use of bow-cases (γωρυτοί) to protect the bows when not in use.

(4) The shape of many ancient bows as rendered in paintings or sculptures.

(5) The manner in which bows the shape of which suggests a composite construction were strung, and the fact (*Odyssey*, XXI.) that considerable knack as well as strength was required for this operation.

(6) Many bows represented in ancient Greek art exhibit asymmetrical curves, corresponding with Strabo's description of Scythian bows.

It seemed probable that the ancient Greeks derived a knowledge of the Asiatic composite bows from the Scythians, either directly through Thrace, or indirectly through Persia and Asia Minor, and the statement made by Pliny, "Arcum et sagittam Scythen Jovis filium, alii sagittas Persen Persei filium invenisse dicunt," may, probably, be taken as reflecting the actual derivation of the Greek composite bow from the Scythians or the Persians.

At the conclusion of the lecture the Huxley memorial medal of the institute was presented to Mr. Balfour by the president, Dr. W. H. R. Rivers.

University and Educational Intelligence.

CAMBRIDGE.—Dr. Haddon, Christ's College, has been appointed acting curator of the Museum of Archæology and Ethnology.

H. F. Holden, St. John's College, has been reelected to the Benn W. Levy studentship in biochemistry.

The Committee for Geodesy and Geodynamics has reported in favour of the erection and equipment of a two-roomed observation building near the Observatory as a first step towards the institution that the committee ultimately aims at to meet the requirements of international geodesy. Further, it is hoped to make provision for study and research in geodesy (including arc measurement, primary triangulation, precise levelling, and gravity determinations), geodynamics, and tidal phenomena. An appeal is to be made for assistance from private benefactions as soon as conditions are favourable.

The Alan Bodey prize of the annual value of 10*l.*, for an essay in applied mathematics, has been founded at Gonville and Caius College.

THE LORD MAYOR OF LONDON tenders his thanks to all who responded to his recent appeal for English books for Latvia. The announcement of the shipment to Riga of several thousands of books (forming the first instalment of the New Year gift of 50,000 volumes which the Lord Mayor hopes, with the further help of the public, to get together) has been received with the liveliest satisfaction in the newly founded Baltic State which has decided to adopt English as its second language and is anxious to assimilate English ideals, particularly in education. Further contributions of English books are solicited. Parcels should be addressed (carriage paid if possible) to Sir Alfred T. Davies, c/o the Consul-General for Latvia, 329 High Holborn, London, W.C.1.

A PROGRAMME of University Extension Lectures for the coming term has been issued by the University of London. Courses of lectures will be delivered at some seventy local centres in different parts of London and its suburbs, and a wide range of subjects is being offered. A few of the courses are of interest to readers of NATURE. Dr. W. B. Brierley is giving a course of twelve weekly lectures on "Some Problems in Modern Biology," which commenced on January 9 at Gresham College, Basinghall Street, E.C., and six lectures on "Inter-racial Problems of Man" at the Central Library, Fulham, commencing on February 7; Mr. J. Lionel Tayler is delivering a course of thirteen lectures at the Morley College, Waterloo Road, S.E., on "Heredity: The Scientific Drama of Personal and Social History," which commenced on January 4; and Prof. F. E. Fritch a course of ten lectures on "Nature Study (Plant Life) in the London Area" at the Central Library, Walthamstow, starting on January 26. Further particulars about the dates and times of the courses available and the fees charged can be obtained from the Registrar of the University Extension Board, University of London, South Kensington, S.W.7.

THE results of an interesting inquiry undertaken by Dr. J. Brownlee, director of the statistical department of the Medical Research Council, are published in the *Times* of January 16. Dr. Brownlee has taken the figures of the census of the British Isles of 1911 and has estimated from them the number of persons of any given age less than twenty-five years at present living in the British Isles and the numbers which may be expected in coming years if the conditions of hygiene represented by the 1910–12 life-table prevail. Taking the age for compulsory education, 5–6 years, the estimated number of children of that age in 1921 is 682,000; in 1922 it is 645,000; in 1923, 568,000; in 1924, 573,000; in 1925, 642,000; and in 1926, 772,000. Put into words, the estimates mean that there will be a decrease in the numbers of children of this age until 1923 and afterwards a rapid increase. Taking the next group, children of 7–12 years of age, the numbers living in 1921 are estimated as 2 per cent. less than those living in 1911, while the estimated population for 1921 between the ages of 12 and 20 years is about 7 per cent. in excess of that of 1911. In no case has account been taken of the effects of the war, emigration, etc., on that part of the population falling within the above groups, but it is considered that no error greater than 1 per cent. is introduced on this account. It will be interesting when the details of the 1921 census of Great Britain are published to see to what extent they are in accord with Dr. Brownlee's figures.

Calendar of Industrial Pioneers.

January 19, 1891. Robert Forester Mushet died.—The son of the discoverer of the black-band ironstone, Mushet made experiments on spiegeleisen—iron and manganese—which proved of great value in the development of the Bessemer process of steel-making. He also investigated alloys of iron with titanium, tungsten, and chromium, and about 1870 introduced the first of the self-hardening steels.

January 20, 1901. Zenobe Théophile Gramme died.—A Belgian carpenter, Gramme went to Paris, where at one time he worked under Ruhmkorff. His fame as an electrician is due to his re-invention in 1870 of the ring-armature dynamo first devised by Pacinotti. A monument to him stands in the Conservatoire des Arts et Métiers in Paris.

January 21, 1901. Elisha Gray died.—A distinguished maker of electrical appliances, Gray took out upwards of sixty patents, and was connected with the Western Electrical Co. of Chicago. On February 14, 1876, he applied for a patent for a telephone only a few hours after Bell had deposited his specification.

January 22, 1831. John Blenkinsop died.—One of the pioneers of the locomotive, Blenkinsop was an agent to some collieries. He took out a patent in 1811, and in 1812 at Leeds constructed an engine with a pinion gearing into a fixed rack. One of his engines was seen by George Stephenson.

January 22, 1887. Sir Joseph Whitworth died.—Among the greatest mechanical engineers of the nineteenth century, Whitworth worked with Maudslay, Holtzapffel, and Clement, and in 1833 set up as a tool-maker at Manchester. He improved machine-tools, perfected measuring machines, introduced standard gauges, and in the 'fifties brought out his valuable system of screw-threads. He also made experiments in artillery and developed the process of compressing melted steel under hydraulic pressure. The Whitworth scholarships and exhibitions were founded by him in 1869.

January 22, 1918. Sir John Wolfe Wolfe-Barry died.—An acknowledged leader in the world of civil engineering, Wolfe-Barry was prominently associated with the transport problems of London. Among his notable works was the Tower Bridge, completed in 1894. He was president of the Institution of Civil Engineers in 1897, and he initiated the Engineering Standards Committees.

January 23, 1805. Claude Chappe died.—The inventor of the semaphore signalling apparatus, Chappe was born in 1763. The statue of him in the Boulevard Saint-Germain in Paris depicts him explaining his invention to the Legislative Assembly in 1792. One of the first messages by semaphore was sent from the roof of the Louvre.

January 23, 1896. Ferdinand Schichau died.—A native of Elbing, where he opened a small shop in 1837, Schichau built Germany's first steam dredger, engined some of the earliest German steam men-of-war, and became a famous constructor of locomotives and torpedo craft.

January 25, 1917. George Andrew Hobson died.—As partner with the late Sir Douglas Fox, Hobson was responsible for many pioneering construction works in America and South Africa, his most remarkable work being the railway bridge over the Zambezi River at the Victoria Falls, the central span of which is 500 ft. long with a rise of 90 ft. He also worked out the plans for generating electricity at the Victoria Falls for the gold-mines of the Rand. E. C. S.

Societies and Academies.

LONDON.

Royal Society, December 8, 1921.—Sir C. S. Sherrington, president, in the chair.—Lord **Rayleigh**: A study of the glow of phosphorus: Periodic luminosity and action of inhibiting substances. The intermittent or periodic luminosity observed when the last traces of oxygen are being removed from air by means of phosphorus, or when air is allowed slowly to leak into an exhausted vessel containing phosphorus, requires the presence of water-vapour. Moderate drying (*e.g.* by sulphuric acid) makes the glow perfectly steady. Water-vapour has therefore the power of inhibiting the combination of phosphorus-vapour and oxygen within certain limits. When the composition of the mixture becomes favourable beyond those limits, a wave of combustion is propagated. Other substances are known to inhibit the glow of phosphorus, and exhibit the above phenomena in a more striking form than water. Camphor, ammonia, and pear-oil are among the most effective. The propagation of these waves of combustion cannot be attributed to the rise of temperature of one layer igniting the next layer, for the rise of temperature is too small. An alternative theory of the propagation is proposed, which assumes that it depends on the provision of nuclei, as in the propagation of crystallisation through a super-cooled liquid. On this basis a theory of the action of the inhibitors or "negative catalysts" is developed.—Lord **Rayleigh**: The aurora line in the spectrum of the night sky. The spectrum of the night sky at Terling (near London) has been photographed systematically. The aurora line at wave-length 5578 Å.U. is recorded on about two nights out of three. Its intensity on ordinary nights is not obviously related either to the amount of magnetic disturbance or to the transit of spots over the sun's central meridian. The intensity in the neighbourhood of Newcastle is notably less than near London, thus the effect appears to increase towards the south. It appears, therefore, to be due to some different cause from the Polar aurora. The aurora line does not coincide with krypton, and experiments to determine its origin gave negative results.—E. F. **Armstrong** and T. P. **Hilditch**: A study of catalytic actions at solid surfaces. VII.: The influence of pressure on the rate of hydrogenation of liquids in presence of nickel. The comparative rates of absorption of hydrogen at different pressures by a variety of unsaturated compounds in presence of nickel have been studied; the relation between the hydrogen pressure and the rate of hydrogenation is dependent on the type of organic compound examined. Simple ethylenic compounds are hydrogenated at rates almost proportional to the absolute pressure of the hydrogen. At very low concentrations of catalyst the increase in rate of hydrogenation becomes less than proportional to the increase in pressure. If the unsaturated compound contains another group which has affinity towards nickel, but is not open to hydrogenation, increase in hydrogen pressure causes an increase in the rate of hydrogen absorption. These results are in harmony with the authors' theory that catalytic hydrogenation is primarily conditioned by an association of the ethylenic linkage with the catalyst, the latter being also associated with hydrogen.—W. D. **Womersley**: The energy in air, steam, and carbon dioxide from 100° C. to 2000° C. Hydrogen and carbon monoxide mixed with either air or oxygen were exploded in a Hopkinson recording calorimeter for explosions. Curves showing the energy in the various gases and

the mean volumetric heats from 100° C. to 2000° C. are given. The values are, where comparable, about $7\frac{1}{2}$ per cent. higher than those of Holborn and Henning. The difficulty in estimating the heat liberated in a closed-vessel explosion is due probably to a spontaneous time reaction between the combustible gas and oxygen when the two are mixed, in which about 10 per cent. of the gas is consumed. The combustion of carbon monoxide is considerably slower than that of hydrogen. This makes the estimation of the heat liberated in the carbon monoxide experiments very uncertain.—J. W. **Gifford**: Atmospheric pressure and refractive indices, with a corresponding table of indices of optical glass. The modulus of rigidity for glass precludes its being sensibly affected by pressure, and therefore any pressure effect must be due to air alone. Two measurements of refractive index of the same wave-length, at different temperatures, are made, and by means of a new formula the refraction temperature-coefficient at standard pressure for 1° C. is determined. Using this as a final correction, indices for other wave-lengths at standard pressure and observed temperature may be brought to standard pressure and temperature (15° C.).—H. P. **Waran**: A new form of interferometer. A thin layer of transparent liquid floating over mercury is employed as a parallel plate interferometer—a substitute for Lummer and Ghercke's glass plate. Viscous castor-oil was successfully used, but its poor transparency stood in the way of securing high resolving power. The disturbing influence of the tremors of the ground was overcome by mounting the trough on a float suspended from the ceiling in a tank of water carried on a massive brick pillar with deep-laid foundations.—H. **Harle**: The viscosities of the hydrogen halides. An experimental determination of the coefficients of viscosity of the gaseous hydrogen halides was undertaken with the view of affording a check upon the theoretical investigation by A. O. Rankine on the diameters of unsymmetrical molecules. The method of continuous transpiration through a capillary tube was employed, using the known data for air. The gases were liquefied, and, by controlling the evaporation, established their own steady pressure while transpiring through the tube. The volumes of gas passing in a given time were found by absorbing in water and titrating with standard alkali solutions. Values of η were obtained at two temperatures, round about 15° C. and 100° C., and from them Sutherland's constant of temperature variation is calculated for each of the gases.

PARIS.

Academy of Sciences, January 3.—M. E. Bertin in the chair.—J. **Effront**: The distinctive properties of amylases of different origins. Specimens of amylase of different origins can be distinguished by the ratio between their liquefying power and sugar formed, by the optimum temperature when acted upon by diastase, and by their resistance to temperatures of 70°, 95°, and 100° C.—P. **Montel**: Quasi-normal families.—M. **Auric**: The generalisation of continued fractions.—MM. **Gossot** and **Liouville**: The principles of interior ballistics.—G. **Sagnac**: Newtonian invariants of matter and of radiant energy and the mechanical ether of variable waves.—H. **Chaumat**: The ballistic galvanometer.—R. **Jouaust**: The reception of waves maintained by modulation. In wireless telegraphy the detectors utilised at the receiving end give a very low yield. In the modification suggested the intensity of the current circulating normally in the receiving apparatus is modulated periodically with a given frequency. A current audible in a telephone is thus obtained the amplitude of which is half that circulating in the receiving apparatus. The method has been applied practically in transmission between Lyons and Paris, and proved to give increased sensibility.—M. **Taffin**: The annealing of glass. The formula given by Kundt in 1881 has been recently shown by Adams and Williamson not to apply rigorously to glass. The author has extended the experiments of Adams and Williamson, and proposes two modifications of their formula. The experimental results are compared with the three formulæ.—R. **Fosse** and A. **Hieulle**: The synthesis of hydrocyanic acid by oxidation, in ammonio-silver solution, of alcohols, phenols, and amines. In presence of ammonia and silver nitrate, hydrocyanic acid is one of the products of oxidation of various alcohols, phenols, and amines by permanganate. Quantitative figures are given for forty compounds, methylamine giving the highest proportion.—L. **Gentil**: The age of the phosphates of Morocco. A study of the fossils in the phosphate deposits of Morocco leads to the conclusion that they are mainly Cretaceous.—P. **Viennot**: The abnormal contact of the north Pyrenean Flysch at the north of Saint-Jean-Pied-de-Port.—P. **Négris**: Atlantis and the quaternary regression. A summary of facts proving a lowering of the level of the Atlantic by the subsidence of the sea-floor, and a discussion of the bearing of these facts on the legends of the submerged continent Atlantis. The facts cited include the form of the submarine floor of the Hudson River, the markings on the Island of Siphnos (Greece) up to a level of 700 metres, and the levels of the wood *débris* deposited by the Gulf Stream on Iceland.—A. **Allemand-Martin**: The lignites of Cap-Bon (Tunis). These lignites are comprised between the levels containing *Turritella fimbriata, Cerithium lignitarum*, and that of *Ostrea crassissima*; they are nearer the Tortonian period than the Helvetian.—L. **Moret**: The presence of limestones containing Alveolina, probably of Auversian age, at the base of the Nummulitic of the Arâche plateau (Massif de Plati, Haute-Savoie).—J. **Savornin**: The watershed of the Oum er Rebia (Morocco) and the general hydrography of the Moroccan middle Atlas.—P. **Lesage**: Study of saline plants during the period in which anomalies are produced.—R. **Combes**: The detection of the pseudo-bases of anthocyanidines in plant tissues. The results obtained by Noack on the extraction of the pseudo-bases of anthocyanidines from plant tissues are shown to be untrustworthy; the colour reactions obtained were probably due to the presence of phlobatannins.—M. **Martin-Zédé**: The influence of orientation on the success of the transplantation of trees. In trees transplanted without reference to their original orientation the loss in the following winter was 50 per cent., but taking care that the sides of the trees facing north were transplanted with the same orientation the loss was reduced to about 7 per cent.—M. and Mme. A. **Chauchard**: The measurement of the excitability of a secretory nerve: tympanic chord and the sub-maxillary gland.—R. **Stumper**: The poison of ants, and in particular formic acid. A proof that no other volatile acid than formic acid is present in ant poison.—A. **Lécaillon**: The characters of a hybrid issuing from the union of *Cairina moschata* and *Chenalopes aegypticus*.—R. **Courrier**: The independence of the seminal gland and the secondary sexual characters in fishes. Experimental study.—R. **Hovasse**: The regulation of the number of chromosomes in the parthenogenetic embryos of the reddish-brown frog. Its mechanism.—L. **Léger** and E. **Hesse**: The coccidia of marsh birds. The genus Jarrina.—A. **Sartory** and L. **Moinson**: A case of bronchial moniliasis. The fungus *Monilia Pinoyi* was isolated from the sputum of a patient suspected of tuberculosis.—

MM. **Rousselot** and A. **Marie**: A peculiarity of audition as a sign of syphilis.—A. **Zimmern** and E. **Salles**: The spectrographic study of the colour change of barium platinocyanide in the Villard effect.

SYDNEY.

Linnean Society of New South Wales, November 30, 1921.—Mr. G. A. Waterhouse, president, in the chair.—R. **Veitch** and W. **Greenwood**: The food-plants or hosts of some Fijian insects. A guide to the economic entomology of the Fiji Islands. The nature of the attack, the economic status of the insect, and the name of its food-plant or host are indicated.—J. G. **Myers**: The Australian apple leafhopper (*Typhlocyba australis*, Frogg.). This species has been introduced into New Zealand, where it does considerable damage to the foliage of apple and hawthorn, signs of its attack being rusty spots and patches on both sides of young and old leaves.—Vera **Irwin-Smith**: Notes on nematodes of the genus Physaloptera, with special reference to those parasitic in reptiles. A list of the species parasitic in each group is followed by a review of those found in reptiles, with special reference to their distribution in Australia. All known reptilian hosts for the genus, with the species parasitic in each, are given.—A. R. **McCulloch**: Notes on, and descriptions of, Australian fishes (2). Most of the fishes discussed were hitherto imperfectly known.—M. B. **Welch**: The occurrence of oil ducts in certain Eucalypts and Angophoras. Ducts occur in the medulla of the stems and leaves of certain Eucalypts of the Corymbosæ class and of *Angophora lanceolata*. They contain oil similar to that in the leaf oil glands—though not directly connected therewith—and function as storage reservoirs. The ducts indicate a primitive character, and show a close phylogenetic affinity between the Eucalypts and Angophoras.

Diary of Societies.

THURSDAY, JANUARY 19.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—S. Gordon: Mountain Birds of Scotland.

ROYAL SOCIETY, at 4.30.—Prof. L. Hill, H. M. Vernon, and D. H. Ash: The Kata-Thermometer as a Measure of Ventilation.—Lt.-Col. C. B. Heald and Maj. W. S. Tucker: Recoil Curves as Shown by the Hot-wire Microphone.—E. W. A. Walker: The Occurrence and Development of Dys-agglutinable, Eu-agglutinable, and Hyper-agglutinable Forms of Certain Bacteria.—Marjory Stephenson and Margaret Whetham: Studies in the Fat Metabolism of the Timothy Grass Bacillus.—J. A. Gardner and F. W. Fox: The Origin and Destiny of Cholesterol in the Animal Organism. Part 12: The Excretion of Sterols in Man.—Dr. S. J. Lewis: The Ultra-violet Absorption Spectra and the Optical Rotation of the Proteins of the Blood Sera.

LINNEAN SOCIETY OF LONDON, at 5.—Dr. E. Marion Delf: Studies in *Macrocystis pyrifera*, the Giant Alga of the Southern Temperate Zone.—J. L. C. Musters: The Flora of Jan Mayen Island.

ROYAL SOCIETY OF MEDICINE (Dermatology Section), at 5.

INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.—J. F. Allan: A Typical Example of Magmatic Injection.—W. E. Whitehead: Steep Sights in Underground Surveys.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.30.—Brig.-Gen. R. K. Bagnall-Wild: Aeroplane Installation.

INSTITUTION OF ELECTRICAL ENGINEERS (Joint Meeting with Institution of Heating and Ventilating Engineers), at 6.—Discussion: The Utilisation of Waste Heat from Electrical Generating Stations, with the following Introductory Papers: C. I. Haden: Utilisation of Exhaust Steam from Electric Generating Stations, and Coal Economy.—F. H. Whysall: The Utilisation of Waste Heat from Electrical Generating Stations.

CHEMICAL SOCIETY, at 8.—Prof. A. Smithells: Models of the Lewis-Langmuir Atom, with Explanations.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (at 11 Chandos Street, W.1), at 8.15.—Dr. E. J. Butler: Some Relations between Vegetable and Human Pathology.

FRIDAY, JANUARY 20.

INSTITUTE OF TRANSPORT (at Royal Society of Arts) (Graduates' and Students' Lecture), at 5.—G. T. Hedge: The Operation of an Important Railway Goods Terminal.

ROYAL ASTRONOMICAL SOCIETY, at 5.—Geophysical Discussion on Isostasy: Capt. Alessio, Col. Sir G. P. Lenox-Conyngham, Prof. Plumbach, and others. Col. H. G. Lyons in the chair.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Hunterian Lecture: The Mongolian Face and its Modifications.

ROYAL SOCIETY OF MEDICINE (Otology Section), at 5.—A. Tweedie: Short Account of the Research Work being conducted in Utrecht on the Saccular, Utricular, and Allied Reflexes (continued).

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—H. S. Denny and N. V. S. Knibbs: Some Observations on a Producer-gas Power Plant.

INSTITUTION OF ELECTRICAL ENGINEERS (London Students' Section), at 7.—L. T. Hinton: Some Applications of the Thermionic Valve to Telephony.

GEOLOGISTS' ASSOCIATION (at University College), at 7.30.—S. Hassledine: Classifications of the Pleistocene Age.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—Lecturette: Geology in its Relation to Engineering.

ROYAL SOCIETY OF MEDICINE (Electro-therapeutics Section), at 8.30.—Dr. Zimmern, Dr. Agnes Savill, Dr. Sloan-Chesser, Dr. C. A. Robinson, Dr. W. J. Turrell, and others: Discussion: Electro-therapy in Gynæcology.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir James Dewar: Soap Films and Molecular Forces.

SATURDAY, JANUARY 21.

BRITISH MYCOLOGICAL SOCIETY (in Botany Lecture Theatre, University College), at 11 a.m.—Dr. W. Brown: The Germination and Growth of Fungi at Various Temperatures and in Various Atmospheres.—Miss D. M. Cayley: Die Back of Stone Fruits due to Diaporthe Perniciosa and the Behaviour of Monospore Cultures in Artificial Media.—W. B. Crow: The Morphology and Affinities of Leuconostoc Mesenteroides.—Dr. H. Wormald: Notes on Crown-gall.—Dr. M. C. Rayner: Obligate Symbiosis in Calluna.—W. J. Dowson: Michaelmas Daisy Wilt.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. C. Macpherson: The Evolution of Organ Music (1).

MONDAY, JANUARY 23.

PHYSIOLOGICAL SOCIETY (at King's College).—Annual General Meeting.

VICTORIA INSTITUTE (at Central Buildings, Westminster), at 4.30.—S. T. Klein: The Invisible is the Real, the Visible is only its Shadow.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Hunterian Lecture: The European Face and its Chief Variations in Type.

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting), at 7.—R. J. Mitchell and others: Discussion: Electric Vehicles: Present and Future.

INSTITUTION OF MECHANICAL ENGINEERS (Graduates' Meeting), at 7.—F. A. Best: Airships.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—Prof. W. Rothenstein: Architectural Draughtsmanship.

ROYAL SOCIETY OF ARTS, at 8.—C. Ainsworth Mitchell: Inks (Cantor Lectures) (1).

MEDICAL SOCIETY OF LONDON, at 8.30.—Dr. F. J. Poynton and Dr. J. W. McNee: A Case resembling Leukœmia, but presenting unusual Clinical and Pathological Features.—T. H. Kellock: A Method of Treating Abscesses.—Dr. W. Broadbent: Observations on Heart Disease.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—C. J. Edmonds: Luristan.

TUESDAY, JANUARY 24.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. F. H. A. Marshall: Physiology as Applied to Agriculture (2).
NEWCOMEN SOCIETY (at Caxton Hall), at 5.—Dr. T. E. Jones: Mechanics of Engineering from the Time of Aristotle to that of Archimedes.
ROYAL SOCIETY OF MEDICINE (Medicine Section), at 5.30.—Dr. C. Boulton, Sir Cuthbert Wallace, Dr. Ryffel, and Dr. A. E. Barclay: Discussion: The Diagnosis of Gastric Ulcer.
INSTITUTION OF CIVIL ENGINEERS, at 6.—A. W. Rendell: Control of Trains, in Relation to Increased Weight and Speed Combined with Reduced Headway.—Sir Henry Fowler and H. N. Gresley: Trials in Connection with the Application of the Vacuum-brake for Long Freight Trains.
WOMEN'S ENGINEERING SOCIETY (at 26 George Street, W.1), at 6.15. —Miss Gwynne Howell: Domestic Engineering.
ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—C. M. Thomas: The Plate and the Photographer.
INSTITUTE OF INDUSTRIAL ADMINISTRATION (at London School of Economics), at 8.—J. M. Fells: Industrial Economics in Relation to the Bearing on National Welfare of the Ascertainment of Cost, with discussion by Sir Lynden Macassey, Sir James Martin, and others.
ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Anniversary Meeting.

WEDNESDAY, JANUARY 25.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Hunterian Lecture: The Study of Certain Aberrant Types: Bushmen, Eskimo, Lapp, and Ainu.
INSTITUTE OF CHEMISTRY (London and South-Eastern Counties Section) (at 30 Russell Square, W.C.1), at 6.—Exhibition of Apparatus other than Glassware.
INSTITUTION OF CIVIL ENGINEERS (Students' Meeting), at 6.—E. W. Monkhouse: The Economic Aspects of Various Methods of Power-transmission.
ROYAL SOCIETY OF ARTS, at 8.—H. M. Edmunds: Photo-sculpture.
ROYAL SOCIETY OF MEDICINE, at 9.—Prof. G. Elliot Smith: The Rhodesian Skull.

THURSDAY, JANUARY 26.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—S. Gordon: Sea Birds and Seals.
ROYAL SOCIETY, at 4.30.—*Probable Papers*.—W. B. Hardy and Ida Doubleday: Boundary Lubrication: The Paraffin Series.—Prof. W. A. Bone, A. R. Pearson, E. Sinkinson, and W. E. Stockings: Researches on the Chemistry of Coal. Part 2: The Resinic Constituents and Coking Propensities of Coals.—Dr. J. A. Crowther and B. J. Schonland: The Scattering of β-rays.—Ann C. Davies: The Minimum Electron Energies associated with the Excitation of the Spectra of Helium.—C. N. Hinshelwood, H. Hartley, and B. Topley: The Influence of Temperature on Two Alternative Modes of Decomposition of Formic Acid.—Prof. C. V. Raman: The Molecular Scattering of Light in Water and the Colour of the Sea.
CONCRETE INSTITUTE, at 7.30.—E. B. Moullin: Capillary Canals in Concrete, and the Percolation of Water through Them.
ROYAL MICROSCOPICAL SOCIETY (Metallurgical Section), at 7.30.—H. Wrighton: Demonstration of Polishing Metal Specimens.
ROYAL SOCIETY OF MEDICINE (Urology Section), at 8.30.

FRIDAY, JANUARY 27.

ASSOCIATION OF ECONOMIC BIOLOGISTS (in Botanical Lecture Theatre, Imperial College of Science and Technology), at 2.30.—Prof. E. P. Stebbing and others: Discussion: The Importance of Scientific Research in Forestry and its Position in the Empire.
ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.—A. L. Howard: The Timbers of India and Burma.
PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.
ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Hunterian Lecture: The Facial Characteristics of the Races native to India.
JUNIOR INSTITUTION OF ENGINEERS, at 8.—L. M. Jockel: Fuels and the Boiler-house.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Viscount Burnham: Journalism.

SATURDAY, JANUARY 28.

ESSEX FIELD CLUB (in Physical Lecture Theatre, West Ham Municipal College), at 3.—C. Nicholson: The Rosy-Marbled Moth (*Erastria venustula*) in Britain (with special reference to Essex). —G. Morris: Some Neolithic Sites in the Valley of the Essex Cam.
ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. C. Macpherson: The Evolution of Organ Music (2).

PUBLIC LECTURES.

(A number in brackets indicates the number of a lecture in a series.)

THURSDAY, JANUARY 19.

KING'S COLLEGE, at 5.30.—Dr. O. Faber: Reinforced Concrete (1).
ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, at 6.—Dr. W. Griffith: Diseases of the Skin Appendages (Chesterfield Lecture).

FRIDAY, JANUARY 20.

METEOROLOGICAL OFFICE, SOUTH KENSINGTON, at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (1).
MIDDLESEX HOSPITAL MEDICAL SCHOOL, at 3.—Sir James Kingston Fowler: Diagnosis (Emeritus Lecture).
KING'S COLLEGE, at 5.—Prof. R. Robinson: Orientation and Conjugation in Organic Chemistry from the Standpoint of the Theories of Partial Valency and of Latent Polarity of Atoms (1).
KING'S COLLEGE, at 5.30.—Rev. Dr. F. A. P. Aveling: Matter, Mind, and Man.

SATURDAY, JANUARY 21.

UNIVERSITY COLLEGE, at 10.30 a.m.—A. Chaston Chapman: Yeast: What it is, and what it does (Lecture for Teachers).
LONDON DAY TRAINING COLLEGE, at 11 a.m.—Prof. J. Adams: The School Class (1).

MONDAY, JANUARY 23.

KING'S COLLEGE, at 5.30.—Prof. C. L. Fortescue: Wireless Transmitting Valves (1).

TUESDAY, JANUARY 24.

KING'S COLLEGE, at 5.30.—F. H. Rolt: Accurate Measurements in Mechanical Engineering: The Use and Testing of Gauges (1).

WEDNESDAY, JANUARY 25.

HORNIMAN MUSEUM (Forest Hill), at 6.—W. W. Skeat: The Living Past in Britain (1).

THURSDAY, JANUARY 26.

UNIVERSITY COLLEGE, at 5.15.—B. S. Rowntree: Industrial Unrest.
KING'S COLLEGE, at 5.30.—Dr. O. Faber: Reinforced Concrete (2).
ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, at 6.—Dr. W. K. Sibley: Alopecia and its Treatment (Chesterfield Lecture).

FRIDAY, JANUARY 27.

METEOROLOGICAL OFFICE (South Kensington), at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (2).
TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES (at the Mary Ward Settlement, Tavistock Place), at 5.30.—Dr. H. Crichton Miller: The New Psychology and its Bearing on Education (1).

SATURDAY, JANUARY 28.

LONDON DAY TRAINING COLLEGE, at 11 a.m.—Prof. J. Adams: The School Class (2).
HORNIMAN MUSEUM (Forest Hill), at 3.30.—F. Balfour-Browne: The Life and Habits of Mason Bees.

The Langley Aeroplane and the Hammondsport Trials.

THE Americans most intimately associated with the work of Prof. S. P. Langley have written to the Royal Aeronautical Society and to NATURE protesting vigorously against the conclusions reached by Mr. Griffith Brewer and summarised in a paper[1] read before the society in October last. The conclusions were[2] :—

(*a*) The Langley machine was not capable of sustained free flight.

(*b*) The Langley machine was not successfully flown at Hammondsport, New York, on June 2, 1914.

The correspondence is published in full in the Journal of the Royal Aeronautical Society, and when discussion is closed it is to be hoped that the society itself will consider the whole matter and express an official opinion. In the meantime it may be assumed that the American presentation of the case is better than that of Mr. Brewer when they claim that in all substantial respects the original Langley aeroplane was capable of sustained flight. It is true that certain modifications were made for the Hammondsport trials which changed the machine in some of its details, but the secretary of the Smithsonian Institution, Dr. Walcott, appears to put the matter very fairly when he says :—

> "I was present at Hammondsport on May 31, 1914, and saw the machine with the original engine giving only two-thirds the original thrust and with wings approximately of the original design, but far rougher executed, get under way from rest and fly gracefully, carrying, besides a man, more than 300 lb. of floats in excess of what the machine was designed to carry. I am still confident that what it did under these relatively adverse circumstances is far inferior to what it was capable of doing in its original condition."

[1] *Aeronautical Journal*, December, 1921.
[2] *Ibid.*, p. 629.

It is much to be regretted that anything happened to prevent a successful flight of the Langley flying machine on October 7, 1903, for no one with an intimate knowledge of the subject can doubt that, aerodynamically and structurally, the machine was good. Aerodynamically it had been preceded by a long series of experiments on a whirling arm, culminating in the flight of a power-driven model based on the results obtained. Although the practical man is loth to admit the fact, it is nevertheless true that the very great bulk of trustworthy information is derived from tests on models by men of science. For very many years to come aviation will continue to draw its inspiration from results obtained on models. Structurally the Langley aeroplane had been carefully made and tested by loading with sand; it is difficult to give credence to Mr. Brewer's suggestion that the structure was obviously defective. Nor is there lack of evidence in the other direction in the later flights. The account of the original failure, vouched for by Mr. C. M. Manly, the pilot on the occasion, is that :—

> "The machinery was working perfectly and giving every reason to anticipate a successful flight, when this accident (due wholly to the launching mechanism) drew the aeroplane abruptly downward at the moment of release and cast it into the water near the houseboat."

This explanation is supported by clear observations of damage to the clutch which held the aeroplane on the launching ways, but is apparently not accepted by Mr. Brewer.

Despite the failure to crown his efforts with a striking popular flight, Langley's work was a very great achievement and removed many difficulties from the paths of his successors, amongst whom were the Wright brothers.

The claims made for Langley by the Smithsonian Institution are :—

> (1) His aerodynamic experiments, some published and some as yet unpublished, were complete enough to form a basis for practical pioneer aviation.
>
> (2) He built and launched, in 1896, the first steam model aeroplane capable of prolonged free flight, and possessing good inherent stability.

(3) He built the first internal-combustion motor suitable for a practical man-carrying aeroplane.

(4) He developed and successfully launched the first gasoline model aeroplane capable of sustained free flight.

(5) He developed and built the first man-carrying aeroplane capable of sustained free flight.

Only the last of these items appears to be in dispute, and, even were adverse criticism justified, the merit of Langley's work would scarcely be affected. It is not disputed on the other side that the Wright brothers made the first sustained flight and so marked a stage of progress which appealed to the world at large instead of to a limited number of men of science. The list of earlier contributors to progress in aviation is long, and all deserve some credit for the ultimate result, but the modern phase took its beginning with the publication of Langley's researches on aerofoils, etc., and the additional spur given by the successful flights of his power-driven models.

It is not too much to say that more original and personal solid work underlay the Langley aeroplane than is the case for any other aeroplane, not excepting those of the present day. The solution of the problems of stability which Langley reached as a pioneer in one instance is still beyond the powers of the majority of his successors in the art of aeroplane design.

Intestinal Protozoa of Man

The Intestinal Protozoa of Man. By Clifford Dobell and F. W. O'Connor. Pp. xii + 211 + 8 plates. (London: Published for the Medical Research Council by J. Bale, Sons, and Danielsson, Ltd., 1921.) 15*s.* net.

THIS is a treatise which will be very valuable to the medical investigator of the microscopic intestinal parasites of man—other than those belonging to the great group of Bacteria. Its origin is due to the continuous and comprehensive study, made during the great war, of the relation to parasitic Protozoa of dysenteric disease occurring in the British Army. Mr. Clifford Dobell has previously published various reports of his masterly work on this subject, and two years ago (December 11, 1919, vol. 104, p. 369) we noticed in these columns his critical essay entitled "The Amœbæ Living in Man." In the present publication Mr. Dobell has been assisted by Mr. F. W. O'Connor, who had independently carried on investigations on intestinal Protozoa in connection with the Egyptian Expeditionary Force. Mr. O'Connor was to have been specially responsible for the medical parts of this book, and Mr. Dobell for those parts which are purely zoological. But, owing to the departure of his medical colleague in 1919 on an expedition to the Gilbert and Ellice Islands, the task of completion of the work and responsibility for the greater part of it have fallen on Mr. Dobell. The treatise is distinguished by that patient inquiry into previous work and critical judgment as to nomenclature and synonomy which have rendered Mr. Dobell's earlier publications of special value. It is absolutely necessary that medical men and protozoologists should agree upon a terminology in order that they may understand each other's writings, and this result Mr. Dobell's careful review and original observations enable them to achieve.

The book is divided into nine chapters, followed by a very complete bibliography and an index and eight plates. Chap. 1 is an introduction to the whole subject, and is followed by chap. 2 on the intestinal Amœbæ of man; chap. 3, Amœbiasis (the name given to infection by Amœbæ, and especially by *A. histolytica*); chap. 4, the intestinal Flagellates of man; chap. 5, the intestinal Coccidia of man; chap. 6, the intestinal Ciliates of man; chap. 7, the diagnosis of intestinal protozoal infections; chap. 8, the treatment of intestinal protozoal infections; and chap. 9, the coprozoic Protozoa of human fæces.

One of the chief sources of error which has to be guarded against by the novice in this study is that of supposing that parasites found in the fæces are necessarily parasites of the intestine. There is a whole series of Amœba-like and flagellate Protozoa which are present in the soil and may obtain access to, and develop in, the fæces after deposition. These are called "coprozoic Protozoa." They may also obtain access to the fæces by means of resistent spores which are swallowed with dust and pass uninjured and undeveloped into the intestinal contents. Apparently the high temperature of the intestine is unfavourable to their development, which occurs only when they have passed to the cooler conditions of the outer world. Many mistaken descriptions of protozoal parasites have been due to this source of error.

The Protozoa which are not merely coprozoic, but actually live in the intestine of man, are only seventeen in number—viz. five Amœbæ, five Flagellata, four Coccidia, and three Ciliata. Some of these are very rare or exceptional; others are abundant, but are not shown to be harmful. Only two which actually sometimes (but not always) destroy the tissue of the intestinal wall or of other organs when present in man are admitted by Mr. Dobell to be pathogenic—viz. *Entamoeba histolytica* and the ciliate *Balantidium coli.* The work of recent years, and much of that of Messrs. Dobell and O'Connor,

has led to this interesting result. The tendency among medical men was to regard every intrusive Entozoon in the human body as "a dangerous parasite," and now we know not only that parasitic Protozoa are not necessarily dangerous, but also that many parasitic bacteria and even some worms are not harmful to their hosts.

Mr. Dobell is inclined to modify the ancient and, as it seems to me, convenient use of the word "parasite." It is not usual to regard every parasite as "a dangerous parasite." One hears of a "harmless parasite" also, and of "mere parasites." In fact, the Greek word means "alongside the victuals," and signified in early times one who had a seat at the table of sacrificial meats—an officially established guest or messmate of the priests. He was "venerable" rather than dangerous, and only when rich men took to entertaining such pensioners for the purpose of display and self-advertisement did "the parasite" fall into contempt and was sneered at as a "toady." The use of the word in zoology has been primarily in accordance with this. The parasite of zoology infests or hangs on to a host from which it obtains shelter and food, but it does not necessarily injure its host. There are many gradations between the harmless necessary parasite and the deadly pest which converts a "host" into a "victim"—absorbing its life-blood or spreading deadly poison into its tissues.

It is difficult to create a terminology which shall in single words indicate the varieties of relationship of parasite and host. The word "commensal" was introduced by the elder Van Beneden. Etymologically it has the same meaning as parasite, but Van Beneden used it to signify specifically an association in which the host suffered no injury or inconvenience, but allowed a distinct species of animal or plant to benefit by the scraps of food rejected by itself, and even to get shelter and carriage by its hospitality. At the same time, Van Beneden pointed out that such close parasitism as that of the intestinal worms is not necessarily injurious to the animals infested, and he cited the fact that, whilst in their normal wild condition the larger carnivorous animals apparently without exception harbour parasitic worms and are perfectly healthy, it is found that the same animals in captivity tend to lose their parasites. They, in fact, become unhealthy and abnormal in captivity. The presence in these animals of a few parasites is (according to Van Beneden) normal and an indication of life in health-giving conditions. For such reasons I should prefer to retain the word "parasite" with its original wide and general meaning, and to classify by name (a somewhat troublesome task) the varieties which it presents.

E. RAY LANKESTER.

Electric Furnaces.

The Electric Furnace. By Dr. J. N. Pring. (Monographs on Industrial Chemistry.) Pp. xii + 485 + 19 plates. (London: Longmans, Green and Co., 1921.) 32*s.* net.

LITTLE more than 100 years have elapsed since the first experiments on electric furnaces were performed, when Davy, in 1810, succeeded in isolating aluminium and the alkali metals by the electrolysis of electrically fused salts. Five years later Pepys carried out experiments on the cementation of iron heated by passing an electric current through it. About half a century elapsed, however, before a commercial furnace was put into operation, one of the earliest being built by the Cowles brothers, at Milton, Staffs. The development that has taken place since that date may be gauged from the fact that the estimated production of electric furnace steel during 1918, in Great Britain alone, was 110,000 tons. This development was largely due to the war and, as the last edition of Stansfield's classic volume (bearing the same title as the book at present under review) is dated 1914, a demand doubtless exists for a further book on electric furnaces.

After dealing with the history and the principles of electric furnaces, the author discusses the types used in laboratory and experimental work. He claims that it is possible to maintain a temperature of 1200° C. inside a tube 8·6 cm. internal diameter, wound with No. 15 s.w.g. nichrome wire. The makers of this material state that it is suitable for use at temperatures up to 1100° C., and while there is no doubt that the higher temperature could be attained, the author was indeed fortunate if his furnace did not burn out in a short time.

The next two sections of the book deal with current supply and transformation in electric furnace operations. These subjects are discussed very fully, commencing with the theory of alternating currents. There is a mistake in the first figure in this section (Fig. 49), both collector brushes of the diagrammatic dynamo being shown on the one slip ring.

A later section, 6, discusses the measurement of high temperatures, dealing mainly with the use of optical and radiation pyrometers. A curious statement occurs on p. 84, where reference is made to thermo-couples consisting of "two different metals such as platinum and an alloy of platinum with rhodium or ruthenium." Surely iridium, not ruthenium, is intended.

The next three sections deal with the chemical,

in contradistinction to the metallurgical, manufactures carried out in the electric furnace, viz. the making of calcium carbide, the synthesis of nitrogen compounds from the atmosphere, and the ammonia oxidation process. In the section on the synthesis of nitrogen compounds it is stated that the world's production of calcium cyanamide during 1918 was estimated to be more than three-quarters of a million tons, of which nearly one-third of a million tons was made in Germany.

In sections 10 to 16 and section 18 an account is given of the use of the electric furnace for the production of metals, alloys, and refractories. The importance of these operations is shown by the fact that, in 1918, 100,000 tons of pig-iron were produced in Sweden in the electric furnace, while during the previous year one and a quarter million tons of electric steel ingots and castings were manufactured in the United States. The section dealing with the manufacture of aluminium is disappointingly short in view of the importance of this metal, about 100,000 tons of which are produced annually at the present time solely by means of the electric furnace.

Attention must be directed to a curious misstatement in this part of the book. It is said (p. 294) that in the electrical smelting of zinc there is a tendency to the formation of a grey powder "due to rapid cooling, whereby the metal passes direct from the vapour to the solid condition, the boiling-point of the metal being only slightly removed from the melting-point." Actually, the boiling-point of zinc, at atmospheric pressure, is more than 900° C., while its melting-point is 418° C. Further, the use of the word "matte" on p. 168 for the metallic product from an iron-making blast-furnace appears to be undesirable.

The remaining sections of the book deal with miscellaneous furnaces, electrolytic processes, and questions of design and power supply.

The book will doubtless be a very valuable addition to the library of the metallurgist and electrical engineer, and it is to be hoped that a second edition will be called for soon, partly to enable the numerous misprints to be corrected. To select a few at random: p. 37, "Electrical connection . . . are conveniently made"; p. 87, an x is evidently omitted from the formula; p. 290, the word "downward" appears to be displaced, presumably from the line above; p. 269, "a Belgian Compant . . ." should doubtless read "a Belgian Company . . ." Furthermore, if the author were to take to heart the dictum reiterated by Rickard in his invaluable book on "Technical Writing" and remember the reader, the demand for a second edition would give him an opportunity of rewriting some of his sentences, particularly the following: "Currents up to 6000 amps. can be lead up to the furnace walls, along two heavy bars for single phase, and three for two or three phase and connected by flexible cables to the electrodes." Or, "According to Prof. J. W. Richards, pig-iron was, in 1920, being produced in Sweden in electric furnaces from charcoal at a cost of 5 dollars per ton less than their own blast-furnace pig-iron."

J. L. H.

Chemistry after the War.

(1) *A Dictionary of Applied Chemistry.* By Sir Edward Thorpe. Assisted by eminent contributors. Vol. 1, *A–Calcium.* Revised and enlarged edition. Pp. x+752. (London: Longmans, Green, and Co., 1921.) 60*s.* net.

(2) *A Text-book of Electro-chemistry.* By Prof. Max le Blanc. Translated from the fourth enlarged German edition by Dr. Willis R. Whitney and Dr. John W. Brown. Pp. xiv+338. (New York: The Macmillan Co. London: Macmillan and Co., Ltd., 1920.) 18*s.* net.

(3) *Thermodynamics and Chemistry.* By Prof. F. H. MacDougall. Pp. v+391. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1921.) 30*s.* net.

(1) IT was almost inevitable that, when the distractions caused by the war had diminished somewhat, there should be a call for a new edition of Thorpe's Dictionary. Whilst pure chemistry may have made comparatively little progress during the war, applied chemistry has received a very great stimulus during the period that has elapsed since the former edition appeared in 1912. The first volume of the new edition has expanded from 614 to 752 pages, or rather more than one-fifth, and whilst it is difficult, without a careful comparison with the old edition, to discover where the expansion has taken place, it is easy to see that the most striking developments are adequately described in the new volume, so far as they are covered by the section from "A" to "calcium." Thus under "acetic acid" and "aldehyde" the manufacture from acetylene is described; under "amatol" there is a forward reference to an article on explosives which will appear in a later volume, and a brief account is given of the new methods used

to prepare ammonium nitrate on a large scale. The synthetic processes for the production of ammonia are described very briefly in a single column, but this is in accord with the classification of the former edition, where a full description of these processes is reserved for a later article under "nitrogen." The revision, as a whole, has been well done, and the new edition can be commended heartily as an accurate presentation of the state of applied chemistry after the vicissitudes of recent years.

(2) The publishers of le Blanc's "Text-book of Electro-chemistry" have adopted a simpler method of meeting the demand for a new edition. Although the title-page is dated 1920, the translator's preface bears no date. No references later than 1907 have been discovered by the reviewer, and the table of equivalents is certainly more than ten years old. In view of the rapid growth of the science of electro-chemistry, further comment is scarcely necessary.

(3) Prof. MacDougall's book contains an attractive and lucid account of the principal applications of thermodynamics to chemistry. The author writes as a chemist rather than as a mathematician, and, instead of giving merely an occasional numerical illustration of his equations and formulæ, has provided quantitative data even when these are scarcely needed to elucidate the text. Thus it is a pleasure to find a full list of specific heats of the solid elements, a table of the heat-capacities of gases and of the ratio of their specific heats at different temperatures, as well as useful tables of the heats of formation of metallic and non-metallic compounds and of heats of solution, combustion, and neutralisation. In the same way the later chapters contain useful tables of electrode-potentials, equivalent conductances, ionisation-coefficients, transference numbers, and ionic conductances. In dealing with the phase rule, one chapter only is devoted to theoretical considerations, whilst three chapters are required to cover the various examples which the author has selected to illustrate the applications of the rule. Another valuable feature of the book is the insertion at the end of each chapter of a large number of problems. These are of a very practical character, and illustrate clearly the many ways in which a knowledge of thermodynamics may be made use of in the study of chemical problems. Certainly no book with which the reviewer is acquainted presents the subject in a manner more likely to prove attractive to the chemist.

T. M. L.

Prices and Wages.

Prices and Wages: An Investigation of the Dynamic Forces in Social Economics. By P. Wallis and A. Wallis. Pp. xii + 456. (London: P. S. King and Son, Ltd., 1921.) 25*s*. net.

THE authors of this volume are, it may be gathered from the preface, business men without much literary experience. The consequent defects of the book, it is to be feared, render it unlikely that many readers will be found with sufficient patience to attempt the whole. Four hundred and fifty pages of reasoning and criticism are at the best a heavy task; when the reasoning is often obscure and unnecessarily verbose, when the criticism seems often ill-informed or based on misunderstanding, the task is apt to become almost unendurable.

The argument appears to be as follows: (1) The value of the net annual production, per head of persons engaged in the industry, for any one commodity, tends to fluctuate in the same way as for any other commodity; this agreement is much closer than for prices. (2) These fluctuations in the value of net annual production are due to fluctuations in the value of the money standard. (3) The value of the net annual production per head, at any one time, tends to be nearly the same for all commodities, including the money standard. (4) Wages and salaries tend approximately to the same proportion of the net annual production per head. (5) It follows from (3) and (4) that the annual wage-rate in any industry tends to be equivalent to the *net* annual production of gold per head for the same grade of labour in the gold-mining industry. (6) The approximately constant proportion of wages and salaries to total net annual product is due to the competition of unemployed labour; the maintenance of this pool of unemployment is the real failure of capitalism.

It should have been obvious even to unpractised writers that ordinary terms should not be employed in senses widely divergent from common usage. This rule has not been followed. The value of the net annual production per head of any commodity is spoken of throughout as its "normal price," with the result that the argument falls at times—for the reader if not for the authors also—into the most hopeless confusion. The reader comes across some phrase about "normal commodity prices"—dissents from it—passes on—and only perhaps some time later when wearied with an argument that seems to him nonsense may it occur to him that the authors did not mean normal prices at all, in the ordinary

 E

sense, but net annual products. Nor is the reader's understanding helped by careful consistence in the use of the term. On p. 116 we read: "This normal price consists in the number of articles produced per person (labour unit) multiplied by the money price," which suggests a gross and not a net product; but on p. 142, "when we take the normal prices which are based upon the unit of labour, we find that this price, *which is the price the producer gets*. . . ."—our italics. On p. 205 we find a clear statement that it is really the net product which is wanted, but on p. 303 we read "normal price is the market price or price per unit, multiplied by the quantity produced." The authors have only themselves to thank if few readers have the patience to stand much loose writing of this sort.

Frankly, this is a pity. For to the present reviewer there seems something to be said for the constructive argument of the book, though very little for much of the criticism contained in it. The argument might have received more attention if concisely presented, with unnecessary criticism eliminated. G. U. Y.

Our Bookshelf.

The War List of the University of Cambridge, 1914–18. Pp. xiv+616. (Cambridge: At the University Press, 1921.) 20*s*. net.

In his address to the Senate of the University of Cambridge, delivered on October 1, 1915, the retiring vice-chancellor, Dr. M. R. James, spoke of the services which members of the university were giving in their country's need. He said: "We are debtors to all. . . . Yet the university bears them upon her heart and will not, I know, neglect to perpetuate the memory of them." No public memorial has, indeed, been raised to their memory, but a noble record has been given to the world by the publication of this volume, which will carry far and wide the names of those members of the university who served with his Majesty's forces.

The volume has been prepared under the able editorship of Major G. V. Carey, of Clare College, and it is based on the lists published from time to time by the *Cambridge Review*, the materials for which came from the various college records. The syndics of the University Press took over the records in December, 1919, and since that date every name has been checked by the official Service Lists. Faced with the task of deciding which names were to be included, it was determined that residence prior to war service should be the criterion, with the exception of those who were prevented from going into residence in October, 1914, by reason of their having joined the forces; further, only those names which appeared in the various Service Lists have been included. This necessarily excludes the names of many who performed valuable and distinguished national service in other capacities, but it is obvious that to obtain an accurate record doing justice to all is almost an impossibility.

The volume concludes with an alphabetical index to the names, and a comprehensive summary—in itself a task of considerable magnitude—giving, for each college and for the whole university, the number of men who served, the number killed in action, the number of honours, etc. The first total is 13,878, and the second 2162—figures which show what a great part the university played in the war, and she has commemorated them worthily in this handsome list.

Meteorological Office—Air Ministry: British Rainfall, 1920: *The Sixtieth Annual Volume of the British Rainfall Organization*. Pp. xxviii+285. (London: H.M.S.O., 1921.) 12*s*. 6*d*. net.

Rainfall statistics over the British Isles have in no way suffered by the transfer of the collection and discussion of the observations from private to public control. The present annual volume is the sixtieth issued, and the second published under the management of the Meteorological Office. The war occasioned some diminution in the number of observers, but a considerable recovery from this is shown, the number now being 4952, an increase of 54 on 1919. A column is added to the detailed observations, giving the number of wet days or days with 0·04 in. or more of rain, and for the present the rain days or days with 0·01 in. of rain are also given.

Standard average values for the period 1881–1915 are used for the first time in "British Rainfall," and these are in agreement with the averages in use by the Meteorological Office in its various publications. Monthly average maps are given for the new period now introduced.

The distribution of total rainfall for 1920 is shown by a map as a frontispiece. Maps of monthly and seasonal rainfall are given, and the peculiarities are well described in the letterpress. Droughts and excessive rains are discussed, and there is much valuable information on evaporation and percolation in 1920.

Special articles are given on the new averages by the Superintendent of the Rainfall Organization, and also on the presence and distribution of salt in the air over the British Isles, by Mr. Wilfred Irwen, and on the Nipher rain-gauge shield, possibly of use where over-exposure is experienced.

Rainfall for 1920 was generally in excess of the average except in the eastern districts of Great Britain. The results for the droughty year 1921 will be of great interest. C. H.

Geography: Physical, Economic, Regional. By J. F. Chamberlain. (Lippincott's School Text Series.) Pp. xviii+509. (London: J. B. Lippincott Co., 1921.) 15*s*. net.

Essentially this book is an account of the earth, its surroundings, and its products in relation to man, but, since it is addressed particularly to

citizens of the United States, nearly all its illustrations, verbal and pictorial, are taken from North America and the possessions of the United States, and all the references, with few exceptions, are to American writers. In view of the fact, admitted by the author, that "the future history of America is to be inseparably connected with that of the rest of the world," more attention might have been directed to other countries; for instance, some of the street-scenes in American cities might have yielded to views in European or Asiatic capitals. It is, however, right that geographical study should begin with the home region, and this idea frequently finds expression in the inquiries suggested at the end of each chapter—*e.g.* "Make a careful study of the influence of geographic environment in your own State or locality. What factors are the most important? Are there any national forests in your State? Locate them. Is the Federal Government aiding in road construction in your vicinity?" But other suggestions will broaden the reader's outlook—*e.g.* "How will the economic geography of France be changed by the restoration of Alsace-Lorraine? What made possible the shipping of meat and dairy products from Australia and New Zealand to the British Isles?" These questions cannot be answered from the book itself. He who succeeds in answering them all will have had to read and think much, and will have become a more valuable citizen.

Modern High-speed Influence Machines. By V. E. Johnson. Pp. viii + 278. (London: E. and F. N. Spon, Ltd., 1921.) 14*s.* net.

THE author points out that electrostatic machines are used much more on the Continent and in America than in this country, where they do not appear to be held in good esteem. He proceeds to argue that this bad repute is undeserved, and proceeds to investigate the capabilities of this class of machine and the conditions upon which its efficiency and trustworthiness depend. Practically all the types which have been proposed from time to time are described and analysed, and accounts are given of the author's own experiments, resulting in a type considerably more efficient than the well-known Wimshurst machine. He claims that, as a source of high potential supply, a high-speed influence machine designed on the right lines should be as efficient as an induction coil with all its accessories, and that, principally on account of the continuity of its supply and the higher voltage available, it should give better results for Röntgen-ray work, particularly with tubes for high penetration. Other fields in which he suggests that such machines may prove useful include applications to wireless telegraphy, electro-culture, electro-therapeutics, ignition, and the testing of materials.

Although we find here and there a little looseness of expression and vagueness in quantitative statement, there is evidence of clear thinking in the construction of a consistent theory of the action of these machines from the mass of incomplete explanation which is diffused among the existing literature on the subject. There is also some thoroughly practical information as to the construction of these machines.

The Transition Spiral and its Introduction to Railway Curves. By A. L. Higgins. Pp. viii + 111. (London: Constable and Co., Ltd., 1921.) 6*s.* net.

THE early part of this book is devoted to a discussion on the principles underlying transition curves. The objects of a transition curve on a railway are to provide a gradual increase in curvature from zero at the point of contact of the curve and the straight part of the line of rails to a curvature equal to that of the central circular portion of the curve, and also to provide for a corresponding increase in the superelevation. Special attention is given to the clothoid (or Glover's spiral) $\lambda = m\sqrt{\phi}$, and the mathematical work required to elucidate this curve is carefully and clearly explained. The conditions which govern the lengths of transition curves are adequately discussed. The engineer may be called upon to insert transition curves in existing lines of railway and also in new lines, and for either purpose he will find the explanations of the procedure given in this book of great service. The latter half of the book is entirely taken up with field exercises fully worked out, which include not only the ordinary problems, but also problems in compound curves and reverse curves. This part is especially valuable, and cannot fail to be of use to railway engineers. We can recommend this book with confidence both to students of surveying and to railway engineers.

The New Hazell Annual and Almanack for the Year 1922. By Dr. T. A. Ingram. Thirty-seventh year of issue. Pp. xlvi + 585. (London: Henry Frowde, Hodder and Stoughton, Ltd., 1922.) 5*s.* net.

THE new volume of Hazell's Annual will receive a cordial welcome from all who have occasion to make use of reference books. It is smaller by about two hundred and thirty pages than the volume issued last year, the sections dealing specifically with the Overseas Dominions and with foreign countries having been omitted, but the omission has enabled the publishers to make a handsome reduction in the price. We also miss several of the interesting surveys of the progress in particular subjects during the previous year which have hitherto been included. Other features of past volumes, such as the calendars, astronomical and meteorological data for the current year, and a compilation of the particulars of societies and institutions, which includes most of the better-known British and foreign learned societies, have been retained. A large amount of educational information which covers the universities, colleges, and secondary schools in the British Isles has also been gathered together. The volume is a valuable book of reference on matters of general interest.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Some Problems in Evolution.

SINCE I am not, in the ordinary meaning, a biologist, I have sometimes difficulty in understanding biological language. Doubtless, also, I am often ignorant of recent developments in knowledge and thought. But certain problems of disease and education interest me, and I cannot get on with them unless some points, essentially biological, are cleared up. In the hope of enlightenment I wrote to NATURE. Immediately the discussion became acrimonious: at least, I became acrimonious. I was told, in effect, that I had no business in the august deliberations of biologists. It is not in human nature, or my variety of it, to accept that pontifical attitude. However, there seems now some prospect of the desired lucidity, and I shall be very ready to accept it with an humble and a contrite heart.

I fear, however, that Dr. Cunningham's letter in NATURE of January 12 does not greatly help. He writes:—"Sir Archdall Reid argues, as though it were a remarkable discovery, that characters are not present as such in the fertilised ovum from which an organism develops." But is that quite fair? I argued only that if, *as all biologists are aware,* no characters as such are present in the germ, then it must follow that, in the case of any and every character, nothing but germinal potentiality (predisposition, diathesis, capacity, ability) to produce (in response to fitting nurture) can be transmitted; whence it follows further that all characters are alike as regards innateness, acquiredness, and inheritability; whence, again, it follows that if we classify characters *with respect to these qualities,* there is, as Prof. Goodrich says, only one kind of character. On the other hand, *as all biologists know* (I protest I do not claim this as a new discovery), there are two kinds of variations: (*a*) those which result from germinal, and (*b*) those which result from nurtural, differences.

Of course, we can classify characters in all sorts of ways, useful and useless—according to colour, weight, size, shape, obviousness of recapitulation, frequency of reproduction, and so on. In a classification which physiologists have found useful, characters are ranked according to the influences which cause them to develop. This tabulation has the merit of forcing the inquirer to bear in mind the plain truth that frequency of reproduction depends (except when germinal variations occur) altogether on the frequency with which fitting nurtures are experienced, and not at all on the frequency of inheritance. For example, under this scheme of classification the inquirer bears in mind that rose comb and single comb in poultry are not more inheritable than corns on oarsmen's hands, but that they are more frequently reproduced only because the proper nurture is more frequently experienced. With respect to inheritance, his mind is fixed on the nature of the individual (the germ-plasm); with respect to reproduction, on the nurture received. Moreover, the student is compelled to realise that when he transfers the distinguishing terms "innate," "acquired," and "inheritable" from likenesses and differences between individuals to the characters in which those likenesses and differences are revealed, he has shifted his ground. It is one thing to compare separate individuals, and quite another thing to compare characters which may occur in the same individual. The old terms may still be applicable; but that is the question which has been raised. It will be gathered that they do not seem applicable to me, and that their constant and (to me) inexplicable transference is one of the causes of my puzzlement. It may be noted also that Darwin, in all that remains permanent of his work, used these terms in relation to variations, while Lamarck and Weismann applied them especially to characters. I may be mistaken, but I believe that I am right when I say that no one (including Darwin) has ever doubted the all-sufficiency of natural selection unless he has, in his thinking, transferred the terms "innate," "acquired," and "inheritable" from variations to characters, or has confused inheritance with reproduction.

Again, we may employ our words with unusual meanings and reason on that basis. Thus "inherit" may be used in the sense of "reproduce," when, of course, the "intensity of inheritance" of combs is infinitely greater than that of corns. But now we are asking for trouble and in sight of confusion. We are in danger of using as counters in thought and discussion, not realities in nature, but mere words. Our inquiries, notwithstanding our language, relate not to the natures of individuals, but to their nurtures. Does or does not the impure dominant inherit the recessive trait which it does not reproduce? Does the pure extracted recessive which is unlike its parent inherit nothing? When a pigeon or a fowl belonging to a fancy breed reproduces the wild ancestral coloration, from whom does it inherit? From an exceedingly remote ancestor? It passes my non-biological comprehension to understand how an individual can inherit except through, and therefore from, his parent. In practice the difficulty is surmounted by using "inherit" with the usual, or with the unusual, meaning as exigencies of argument dictate. For example, Dr. Cunningham employs the word with the ordinary meaning when he declares "a character may be inherited when it is apparent only in one parent or in neither," and with the unusual meaning when he insists that combs are more inheritable than corns.

Consider the Lamarckian dictum: "Acquired as well as innate characters are inheritable"; and the neo-Darwinian: "Innate, but not acquired, characters are inheritable." What do "innate" and "acquired" mean here? No one can tell. Definitions are impossible, for none can be framed which cover the whole of common and accepted usage. What does "inherit" mean? When applied to "innate" characters it may have, as already indicated, its ordinary meaning, or it may mean "reproduce." If a cock reproduced a comb under the same conditions as those in which its parent produced it (in response to similar nurture) all biologists would regard the comb as inherited—and rightly, for reproduction *under the same conditions* implies inheritance, though inheritance does not necessarily imply reproduction. The case is different with respect to "acquired" characters. If a child reproduced an oarsman's corn under the same conditions as the parent produced it, few biologists would regard the corn as inherited. It would be regarded as inherited only if the child developed it under conditions in which the parent did not and could not have developed it. The word now means "vary," *i.e.* non-inherit, for non-inheritance *is* variation. It seems, then, that an acquired character is not inherited when it is inherited, and is inherited when it is not inherited—*i.e.* a single word in a single sentence has two con-

trary meanings. Biologists say they understand one another, and therefore I suppose they do; but I wish, in pity, they would enlighten me. Why do Lamarckians and neo-Darwinians say "inherit" when they mean "vary"? Why do Mendelians and biometricians say "inherit" when they mean "reproduce"? Meanwhile, I cannot help suspecting that something is wrong. Consider what has happened—Lamarck's theory and half a century of stasis; Darwin's brilliant lucidity and twenty years of progress, with biology in its splendour, a great intellectual force; Weismann's effort, and nearly half a century of controversy, with interest in the subject limited to some (not all) zoologists and botanists, and of these few a majority resentful of trespassers.

I propose in two or three letters to adopt the physiological classification when dealing with three or four biological subjects. Biologists, I hope, will be tolerant towards one who uses this classification because, admittedly, he does not understand the difficult language they speak. G. ARCHDALL REID.

9 Victoria Road South, Southsea, January 16.

Atmospheric Refraction.

DR. BALL is surely wrong in suggesting in NATURE of January 5, p. 8, that the difference between Mr. Mallock's figure for the radius of curvature of a nearly horizontal ray and that given by Dr. de Graaff Hunter is accounted for by any consideration of the curvature of the wave-front. If such were the case, then an observer looking towards the sea horizon would see a ray of light in different directions for different initial curvatures of the wave-front. Suppose an observer from the bridge of a ship were looking at a searchlight placed at sea-level at the extreme limit of visibility. The rays of the searchlight beam would be plane waves, those coming from the barrel of the searchlight spherical. Does Dr. Ball wish us to infer that in such circumstances the visible beam would appear to the observer to issue from a point *above* the projector?—for that is what his suggestion leads to.

To my mind, a great deal of the confusion between refraction figures given by different authorities lies in their attempt to connect refraction with variations of temperature before they have properly considered the subject from the point of view of variations in refractive index. If we assume that, over the sea at all events, the refractive index stratification is one which is spherical and concentric with the earth, then the general equation of any ray of light is

$$pn = \text{constant},$$

where n is the refractive index and p the perpendicular upon the tangent to the ray from the earth's centre (see Herman, "Geometrical Optics," p. 305, or Heath, "Geometrical Optics," p. 329).

If r is the distance of any point upon the ray from the earth's centre, h the height of the point above the earth's surface, and R the earth's radius, then $r = \mathrm{R} + h$.

Now n must be some function of the height $= f(h) = f(r - \mathrm{R})$, and hence the "$p, r$" equation of the ray is

$$pf(r - \mathrm{R}) = \text{constant} = \mathrm{C}.$$

The radius of curvature of the ray is thus

$$\sigma = r\frac{dr}{dp},$$

$$= -\frac{r\{f(r-\mathrm{R})\}^2}{\mathrm{C}} \Big/ \frac{df}{dr},$$

or

$$= -\frac{rn^2}{\mathrm{C}} \Big/ \frac{dn}{dh}.$$

As we are dealing with a ray which is nearly horizontal, variations in r and n^2 cannot have large effects upon σ. The variations in r might amount to 1 part in 200,000 if the ray never gets above 100 ft. above the surface of the sea; the refractive index, which at the sea-level is 1·00029, could scarcely be reduced below 1·00027 in the same height, so that variations in n^2 could not exceed 4 parts in 100,000. It follows that the curvature of such rays is essentially proportional to the refractive index gradient. Since by Dale and Gladstone's law $n - 1$ is proportional to ρ, the density, the curvature of the ray-path becomes immediately proportional to the density-gradient. If we attempt to translate density-gradient into temperature-gradient, I see no means of doing so other than by making the assumption that the atmosphere is statically in equilibrium, in which case the formulæ given in my letter in NATURE of January 5 result immediately. But I have the gravest doubts of the legitimacy of such an assumption for the lower levels of the air. A steady motion leading to a dynamical relationship between pressure, density, and temperature is much more likely, but is, from the mathematician's point of view, a hopeless thing to try to set down owing to the impossibility of dealing with all the factors of the problem, such as rate of radiation of heat-energy from the earth or sea, rate of thermal conduction in the air, nature of the upward air-currents, and so on.

If however, we leave all such considerations aside and deal only with the established connections between curvature of the ray-path and the density-gradient, then we can only admit uniform curvature if we are prepared to admit that the density of the air in its lower levels is a linear function of the height. To such an admission I take the strongest exception. It is quite insufficient to account for a refraction of the visible sea horizon above the true horizontal—a phenomenon which, as every seaman knows, is by no means uncommon. T. Y. BAKER.

Admiralty Research Laboratory, Teddington,
Middlesex, January 7.

The Colours of Tempered Steel.

THE well-known and characteristic tints that appear on the surface of a tarnishable metal when it is heated in contact with air have been usually regarded as interference colours due to the formation of a thin film of oxide on the surface of the metal. The correctness of this explanation has, however, recently been questioned (A. Mallock, Proc. Roy. Soc., 1918), and rightly so, as a continuous film on a strongly reflected surface cannot on optical principles be expected to exhibit such vivid colours as those observed.

I have recently made some observations which shed a new light on this subject. It is found that the *missing colours* complementary to the tints seen by reflected light appear as light *scattered* or *diffracted* from the surface of the metal. In other words, if a plate of blue-tempered steel be held in a beam of light and viewed in such a direction that the regularly reflected light does not reach the eye, the metal shows a straw-yellow colour, and not the usual blue. It will be understood that the scattered light, being distributed over a large solid angle, appears much feebler than the regularly reflected colour, and in order to observe the effect satisfactorily the metal should have a smoothly polished surface before being heated up. Scratches and other irregularities show the ordinary colour of the film, and not the complementary tint. The most attractive effects are those exhibited by a heated copper plate, both on account of the vividness

of the colours and on account of the ease with which the surface can be given a satisfactory polish.

It is clear from the observations mentioned above that the colours under discussion are in the nature of *diffraction effects* arising from a film which is not continuous, but has a close-grained structure. Interesting effects are observed when the surface of the illuminated plate is viewed through a nicol, the colour and intensity of the scattered, as well as of the regularly reflected, beams varying as the nicol is rotated about its axis. The most striking effect is obtained when the direction of observation is nearly parallel to the surface of the plate. The scattered light in this case is nearly completely polarised, and the colour of the regularly reflected light changes nearly to its complementary when the nicol is turned through 90°. The phenomena strongly recall to mind the observations of R. W. Wood on the colours of a frilled collodion film on a silvered surface, which have been discussed by the late Lord Rayleigh (*Phil. Mag.*, November, 1917), and it seems probable that the explanation of the phenomena will ultimately be found to be somewhat similar in the two cases.

C. V. RAMAN.

210 Bowbazaar Street, Calcutta, India,
October 11.

MR. MALLOCK has shown that the colour of the oxide film is an *intrinsic* property of the material of which it is composed and the material retains this property as it is gradually ground down from its original thickness to the vanishing point. Sir George Beilby's observations have confirmed this, and have further shown that the film is an aggregate *in open formation* through which oxygen molecules can penetrate to the metallic surface. For each temperature above the tempering range the thickness of the film is determined by the porosity of the aggregate to the oxygen molecules at that temperature. Direct experimental observations have shown the part played by *time of heating* at any given temperature. For example, at 275° C. a deep purple was reached in ten minutes, and this changed to blue from the margin inwards during a further period of twenty minutes. It was thus shown that the watchspring-blue, which could immediately be produced by a temperature of 300° C., could also be produced by heating at 275° for thirty minutes. Sir George Beilby's view is that the *intrinsic* colours of the films which are produced at different temperatures result from changes in molecular aggregation in relatively open formation of a similar nature to those which have been shown to occur in thin metal films, *e.g.* gold. This is referred to in his recently published volume entitled "Aggregation and Flow of Solids," sections 3 and 10.—ED. NATURE.

Some Terrestrial Experiments on Gravitation and Einstein's Theory.

THE object of this letter is to direct the attention of writers on Einstein's theory of gravitation to some recent experiments on the terrestrial aspects of gravitation which seem to have been overlooked, although they appear to be of great importance for the purpose of forming a just estimate of the correctness of Einstein's theory.

The first investigation referred to is that of Dr. P. E. Shaw on the effect of temperature on gravitative force (Phil. Trans., 1916, A, vol. 216, pp. 349–92). On p. 390 Dr. Shaw writes:—"When a large mass attracts a small one, the gravitative force between them increases by about 1/500 as the temperature of the large mass rises from, say, 15° C. to 215° C." The only cause capable of producing this effect on the relativity theory seems to me to be the absorption of heat by the large mass (lead), amounting to 6 calories, or $2\cdot5\times10^8$ ergs per gram, and resulting in a fractional increase of inertial mass of about $2\cdot8\times10^{-13}$. We require 7000 million times this amount in order to account for Dr. Shaw's result on the hypothesis of the proportionality of the gravitative and inertial masses, which is one of the basal assumptions of Einstein's theory.

Another investigation is that of Majorana on the absorption of the gravitational flux (*Phil. Mag.*, vol. 6, No. 39, pp. 488–504, 1920), in which he finds, *inter alia*, that a lead ball weighed *in vacuo* loses $7\cdot7\times10^{-10}$ of its weight when it is surrounded symmetrically by 104 kg. of mercury. If the gravitational flux be assumed to be absorbed by the mercury according to an exponential law of density and thickness, the *quenching constant*, or factor of absorption, is found to be $6\cdot73\times10^{-13}$ per unit density and length. A possible interpretation is that the gravitational mass of a homogeneous sphere at an outside point is only a fraction of its inertial mass; according to Majorana, it is about one-third for the sun. If this interpretation be legitimate, the results of Majorana, like those of Shaw, lead to the conclusion that the gravitational and inertial masses are not proportional to one another in all circumstances.

British Scientific Instruments.

IN the timely and encouraging leader in NATURE of January 19, with which my experience is in entire agreement, there is a point of some importance to which reference is omitted. This is the practical question of cost. I would ask permission to draw a moral for application at the present time. Without expressing any opinion as to whether this cost could be reduced by improved methods of manufacture, I would direct attention to the fact that in the impoverished state of the finances of universities and similar bodies it is impossible adequately to equip their laboratories with costly apparatus.

The moral is this: *The most effective way in which Government intervention can assist British makers of scientific apparatus is to increase the grants to universities and to research in general.* It is impossible for individual workers to purchase expensive British instruments out of their own incomes, and until the resources of the laboratories in which they work are sufficiently increased it is an unjustifiable and foolish restriction to prevent their obtaining from abroad apparatus often admittedly inferior, but capable of good use. How many laboratories can afford to obtain Hilger optical apparatus or the Cambridge string galvanometer? It is further to be remembered that as science advances the instrumental equipment for continued pushing forward tends to become more elaborate, sensitive, and accurate, and necessarily of greater cost

W. M. BAYLISS.

University College, London.

Globular Lightning Discharge.

THE following is an account of what appears to have been a genuine case of globular electrical discharge observed by the sisters of one of my colleagues, the Misses Pitman, at Eastbourne on August 17 last. Authentic instances of this phenomenon are rare, and as the conditions which accompanied this particular

ball were observed with some care it seems desirable to put the case on record.

The two ladies were sitting at table about 8 p.m., with the window open. It was raining heavily at the time, and there was no wind. Stormy clouds were about, but it was not unusually hot. Thunder and lightning at the same time were afterwards reported from London—a distance of, say, 50 miles—but there was no thunderstorm at Eastbourne. There had been no rain during the few preceding days. As one of the ladies took up a knife to cut bread the ball of light was seen to flash past the knife (without touching it) on to the table, travelling a distance of about 9 in. at an average height of about 3 in. from the table, but moving towards the latter.

When the ball touched the tablecloth it "went out with a spitting sound," leaving no mark or trace of any sort. Until it touched the cloth there was no sound, and the whole thing was over in such a "flash of time" that it was impossible to say how fast the ball travelled. There seems to have been an impression that the ball came from the direction of the open window, but it was only under dependable observation during its 9-in. path from the bread-knife to the tablecloth.

As to the appearance of the ball itself, it was "about the size of a pea, the light encircling it being about the size of a golf ball. The light was white and intensely bright, like electricity." "Too dazzling to see through." A. P. CHATTOCK.

The University, Bristol.

Where did Terrestrial Life Begin?

FOR a long time now the idea has prevailed that life began in the sea or in the mud of the seashore, and many interesting articles have been written to describe the emigration of sea-creatures and water-creatures to the land, but there are some difficulties in the way of this theory which do not seem to have been noticed, and on broad general grounds it is, perhaps, more probable that life began on mountain-tops.

Life became possible on the earth only after it had cooled to a certain point, and surely that point was reached much sooner on hilltops than in the sea or on the seashore. It must be remembered that the sea when first formed would have a temperature of more than 100° C., since the condensation of volcanic steam must have taken place under a massive atmosphere of carbon dioxide. This heavy atmosphere would not only raise the boiling point of the sea, but would greatly retard its cooling, which would in any case be a very slow process, since the sea-bed would be hot and the sea deep, and a bad conductor. Would not the mountain-tops have become cool and habitable centuries before the temperature of the sea fell to 111° F. and became a fit abode of life? Further, it is almost certain that the first life was green chlorophyll-carrying cells which would require sunlight, and sunlight would pierce the heavy and cloudy atmosphere of steam and carbon dioxide, and would reach the hill-tops long before it reached sea-level.

For these reasons it seems that life is more likely to have made its first appearance on the mountain-top of the Polar regions than in sea-mud or sea-water. RONALD CAMPBELL MACFIE.

DR. MACFIE's suggestion that life originated on the mountain summits is new, and entitled to careful consideration. If the early earth, when its atmosphere was laden with carbon dioxide and steam, had been windless, then the mountain summits would have stood like islands above a sea of hot mist, and they would have been the only situations possible for the development of life; but as any wind would have at times submerged the mountain summits beneath the lower atmosphere, they would have been subject to violent fluctuations in temperature and moisture which would have been unfavourable to primitive life. It may be doubted whether life could have appeared on the earth until later, when the temperature and the atmosphere were more similar to those which have existed throughout all the time of which there are contemporary geological records as to climate and geographical conditions.

In the discussion on this question in a chapter of "The Making of the Earth" I laid stress on an equable environment as an essential condition for the development of Protobion, the most primitive form of life. If that view be sound, then life was not likely to have developed until a considerably later stage on the earth than that at which the conditions stated by Dr. Macfie would have held. His letter involves the issue whether the first life was semi-aquatic or terrestrial. On his assumption that it is "almost certain" that the first life consisted of cells containing chlorophyll it would certainly have begun on land. But such an organism would be more complex, and, therefore, probably later in development than some simple form of amœboid or mycetozoon, to which strong sunlight would have been less beneficial, and for which the unchanging environment on the muddy shores of a primeval lagoon would appear to be a more suitable medium than a mountain summit.

Rainfall and Drainage at Rothamsted in 1921.

IN view of warnings that are being issued by various water companies that waste of water should be avoided, the rain and drainage figures of the Rothamsted Experimental Station for 1921 are of considerable interest and significance. The drainage gauges were built in Barnfield in 1870 by Lawes and Gilbert, and contain undisturbed soil which is kept bare; each gauge measures 1/1000 acre. The soil is a rather heavy loam with a reddish subsoil over chalk.

	Rainfall	Percolation.		
	1/1000 acre gauge. Inches.	Through 20 inches of soil. Inches.	Through 40 inches of soil. Inches.	Through 60 inches of soil. Inches.
For year 1921	16·093	5·766	5·984	5·479
Average for 50 years ...	28·692	14·834	15·482	14·659

The significance of these figures is that not merely is the rainfall and drainage the lowest since the records started, but that whereas in a normal year about 50 per cent. of the rainfall evaporates, during the past twelve months as much as 63 to 65 per cent. evaporated. This is partly accounted for by the excess of sunshine, which at this station amounted to 159 hours above the average, or about 26 minutes a day.

The number of days on which rain fell (0·01 in. or more) during the past twelve months is 119; this compares with an average for sixty-eight years of 174.

It is interesting to recall the fact that the year 1902, which hitherto gave the lowest percolation figures, was followed by the wettest year on our records, when the heavy rain-showers gave a drainage of 24 in. W. D. CHRISTMAS.

Rothamsted Experimental Station, Harpenden, January 16.

Tribal Name of the Raninidæ.

In the report of the Linnean Society's meeting on December 15 last the abstract of an elaborate and highly important essay by Prof. G. C. Bourne on "The Raninidæ: A Study in Carcinology" contains a proposal to place the family "in a separate tribe, Gymnopleura."

It would seem, however, that the name for such a tribe has been anticipated by Latreille, who, under date 1831, in his "Cours d'Entomologie," p. 368, institutes the tribe Notopterygia expressly for the genus Ranina. Attention has been directed to this in the comparatively recent year 1908 in the Annals of the South African Museum, vol. 6, p. 17. The same page explains that the specific name in *Ranina dentata* is founded on a mistake, and the preceding page, while giving a wrong date to the Mantissa of Fabricius, will by its synonymy justify the substitution of *Ranina raninus*, Linn., in preference alike to *R. scabra* and *R. dentata*.

THOMAS R. R. STEBBING.

Tunbridge Wells, December 22.

I AM far from a scientific library and unable to verify Mr. Stebbing's reference to Latreille's classification of the Raninidæ, but have not the least doubt that the reference is correct. There is no reference to Latreille's tribe Notopterygia either in Milne Edward's "Histoire Naturelle des Crustacés" or in de Haan's "Crustacea" in Siebold's "Fauna Japonica," and as I was concerned rather with the correction of existing schemes of classification than with the work of earlier authors, Latreille's "Cours d'Entomologie" escaped my attention. Had I read it I should have suggested the restoration of Latreille's tribe, giving to it the new definition set forth in my memoir communicated to the Linnean Society, and it seems that my proper course will be to withdraw the name "Gymnopleura" and substitute that of "Notopterygia, Latreille," in an addendum to the printed paper.

The Depth of Earthquake Focus.

In the Philosophical Transactions of the Royal Society, Series A, vol. 222, pp. 45–56 (1921), Mr. G. W. Walker, relying on certain observations of the emergence-angle of P waves at Pulkovo, makes the somewhat startling suggestion that the depth of focus is of the order one-fifth of the earth's radius, or about 1250 km. This is a much larger estimate of depth than that hitherto suggested, viz. of order less than 100 km. Mr. Walker's estimate of depth is a consequence of accepting the Pulkovo numbers as correct. It appears that the values of the apparent angle of emergence calculated from Zöppritz's curve do not agree with its value directly measured at Pulkovo. This discrepancy is so marked that either the time-curve or the Pulkovo values must be seriously in error, and Mr. Walker proceeds on the assumption that within the limits of possible error in the time-curve we can modify it so as to agree with the direct measure of the apparent angle of emergence.

It appeared to me that in a matter so important independent proofs would be desirable, and an attempt has been made to obtain an estimate of depth from the following considerations:—For a very deep focus, the long-wave phase in the seismogram or the "main strock" identified with the arrival of Rayleigh's two-dimensional surface-waves would be of diminished importance compared to the P and S phases which are due to the three-dimensional longitudinal and transverse waves travelling by brachistochronic paths from focus to station, in view of the fact that the surface-waves are originated by the shocks in the epicentral region. These shocks in their turn are due to the arrival of the longitudinal and transverse waves from focus to the epicentral region, and these waves, varying as they do as the inverse powers of the distance, make the shock in that region of lesser and lesser intensity the greater the depth of the focus. Consequently, the depth to be chosen for the focus must be of such a magnitude that the observed relationship between the principal phases in the seismogram is maintained. It has been found possible to calculate the effects of various focal depths on the relative importance of the different phases in the seismogram by an extension of the procedure adopted by Lamb in determining the propagation of tremors on the surface of an elastic solid (Phil. Trans., A, vol. 203, 1904). The investigation suggests that the hitherto accepted estimate of depth of focus is much nearer the truth than Mr. Walker's estimate. The detailed calculations will be published in due course.

Energy Changes Involved in Transmutation.

In some recent discussions concerning the possibility of the transmutability of large amounts of one element into others—and particularly that of lead into gold—no mention has been made of the energy changes involved. Studies in radio-activity and the work of Sir Ernest Rutherford have shown that whenever an element breaks up a relatively enormous quantity of energy is liberated.

Should it ever become possible to control the breaking up of elements, the advantages to be gained will lie in two main directions. First, the manufacture of elements now scarce from those more plentiful will be of the utmost value to industry. Secondly, the fact that intra-atomic energy will then be available should provide a satisfactory solution to the problems raised by the world's dwindling sources of power.

But if the energy available in this way is ever extensively used, all the heavier elements will be destroyed and gradually replaced by lighter; at the same time their available energy will be lost. So it appears possible that after countless ages the earth may become a mass of light elements, possibly in the condition of a nebula.

It has been assumed above that it would be possible to control the decomposition of elements so that only a limited amount of energy was liberated at a time. It is of some interest to contemplate what will happen should this evolution of energy get out of hand.

Let us suppose that someone has succeeded in starting the rapid decomposition of a block of a heavy element by the use of some accelerating influence. If the energy liberated during the action can escape faster than it is set free, no violent action is to be expected; but if, on the other hand, it is liberated faster than it can escape, an action of explosive violence may occur. The accumulation of energy will certainly increase the rate of decomposition of surrounding atoms, which in their turn will add still more energy, and the change will go on with ever-increasing velocity until the whole block of the element is destroyed. Should the surrounding elements be unable to stand up against the enormous quantity of free energy at their surfaces, it seems that nothing could save the earth from complete destruction. Thus inadvertently the world might be reduced by some enterprising chemist or physicist to a white-hot nebulous mass.

The Theory of the South-West Monsoon.

By L. C. W. BONACINA.

IN the widest sense the term "monsoon" in climatology is applicable to those seasonal modifications, or subversions, of the planetary circulation which are established by the differences of temperature due to the irregular distribution of land and water, especially as seen in such regions as Eastern and Southern Asia, where a definite continental outflow of air in winter, and inflow in summer, characterise the surface circulation.

In relation to India the expression "south-west monsoon" is nowadays quite a commonplace, but it cannot be said that the theory of the phenomenon has hitherto been properly elaborated. The text-books commonly describe the monsoon as a kind of magnified sea-breeze action, an explanation of a complex phenomenon which can stand only as a first approximation. It must be emphasised, indeed, that the south-west monsoon of India is not in the main a special local effect of the heated condition of India at all, but is part of a general circulation of air with respect to a system of low barometric pressure originating primarily in the heated condition of the vast Asiatic continent as a whole. It is when one abandons a merely qualitative conception of the monsoonal circulation and considers the latter in the form which it actually takes as a wind-system of particular direction, speed, and structure that the mechanism is realised to be much more complex than is suggested by the above simple statement. For, just as one cannot understand the many puzzling peculiarities of the small-scale diurnal sea-breeze effect familiar round the English coast in summertime without referring to the general barometric-gradient wind of which it is often nothing more important than a coastal modification in direction and speed, so one cannot properly deal with the large-scale seasonal sea-breeze effect in monsoon countries otherwise than as an item in a wider system of circulation. This outlook is the key to the problem, and has enabled Dr. G. C. Simpson[1] to present meteorologists with the most effective analysis that has yet appeared. He shows the futility of trying to explain the monsoon in terms of a single cause, and the necessity of seeing in the phenomenon the final result of a number of interacting factors.

Before stating Dr. Simpson's theory, it may be well to review the main seasonal divisions of the Indian year. These are: (1) a cool, dry season, November to February, definitely dominated by the north-east monsoon, which really belongs to the north-east trade system as regulated at this season by high barometric pressure in Central Asia; (2) a hot, dry season, March to May, characterised by light air-currents gradually changing round from north-east to south-west,

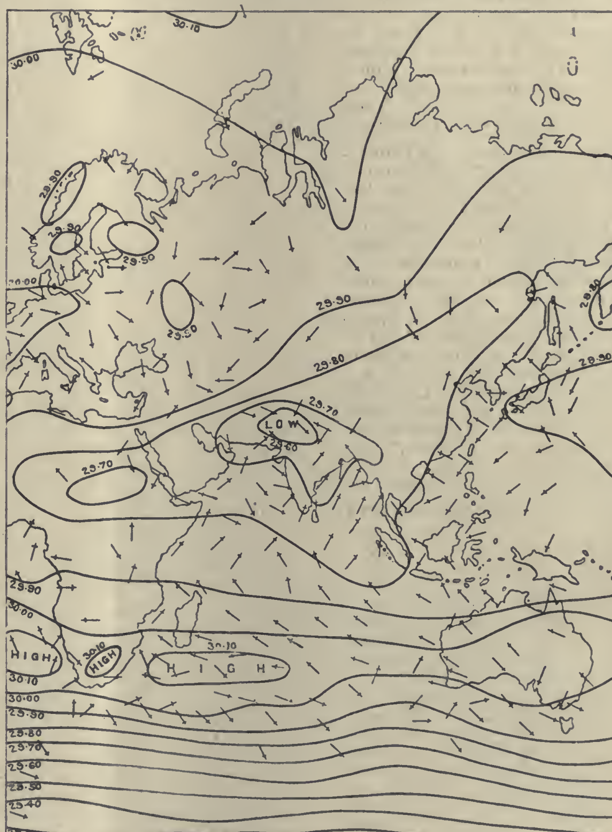

FIG. 1.—Average wind and pressure distribution around India in May. Pressure in inches.

[1] "The South-West Monsoon. Lecture delivered to the Royal Meteorological Society, March 16, 1921, and published in the Society's Journal for July, 1921.

culminating in unstable conditions productive of violent thunderstorms; (3) a wet season, June to September, dominated by the south-west monsoon, a powerful current bringing heavy rainfall everywhere in India except the north-west corner and those parts situated on the lee side of the mountain ranges; (4) a short transition period embracing the month of October, during which the south-west monsoon is retreating with belated rains on the Madras coast.

Now, in order to strike at the root of the prevalent misconception that the south-west monsoon current is due essentially to the heated surface of India itself, Dr. Simpson points to the outstanding seasonal anomaly in the climate of India. The anomaly in question is the fact that the hottest month of the year in India as a whole is not July, but May, coming, that is to say, just before the high solstice, instead of just after, as in England and most countries. The mean day and night temperature for the whole of India in May is 88·7° F., with a large part of the northern central region more than 90°, whereas in July the mean is only 83·5°, with the area more than 90° relegated to the Thar Desert in the north-west.

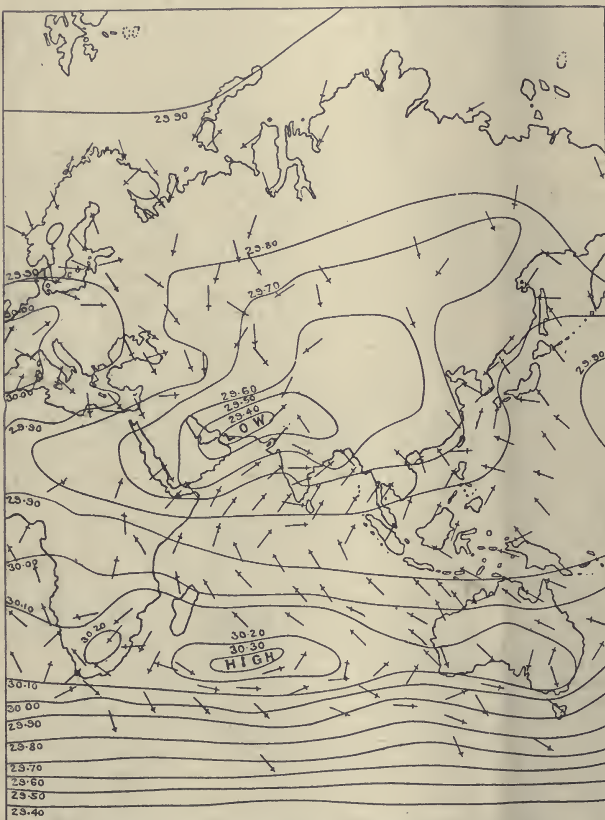

FIG. 2.—Average wind and pressure distribution around India in July. Pressure in inches.

Clearly, in all the more northern portions of India which lie away from the nearly non-seasonal equatorial regimen controlling the climate of Ceylon and the extreme south of the peninsula, the temperature ought to continue rising until July, and the fact that after May it appreciably declines is evidently the result of the cutting off of sunshine by the dense canopy of cloud and rain rolled in by the south-west monsoon. Why, then, does not the south-west monsoon burst in May? Because in that month the summer low-pressure system to the north-west of India is not in a sufficiently advanced stage of development. It is not until June that this low-pressure area and, contemporaneously, the high-pressure area in the South Indian Ocean become pronounced enough to induce the south-east trade wind to cross the equator, thereby to become deflected by the rotation of the earth into the current which feeds the south-west monsoon. The difference is illustrated in Figs. 1 and 2, which show the average distribution of wind and pressure over a large area surrounding India in May and July. The difference between the two maps will be brought out more fully in relation to the monsoon rainfall. Meanwhile, let there be noted what is exhibited with much greater distinctness in maps[2] of wind and pressure for India alone, that in both months, but more conspicuously in May, the isobars, with corresponding deflection of the wind arrows, bend southward in crossing the Indian land-mass—away, that is to say, from the centre of low pressure in the north—signifying that there actually is some indraught due to India itself, though it is only a superposed secondary feature, giving the isobars their precise trend—a local modification of the general Asiatic circulation.

Now to explain the great meteorological characteristic of the south-west monsoon, viz. the heavy rainfall. The diagram Fig. 3 was devised by Dr. Simpson to represent the chief alignments of mountains in and around India (thick-lettered lines), and the chief air-stream lines of the south-

[2] See Dr. Simpson's original paper, and Sir John Eliot's "Climatological Atlas of India."

west monsoon current (numbered arrows). It should be studied in relation to Fig. 4, showing

FIG. 3.—Chief alignments of mountains, and air-stream lines of south-west monsoon, in and around India. (After G. C. Simpson.)

the mean rainfall over the same area in July, the typical monsoon month. The disposition of the mountain ranges is such as very effectively to entrap in a kind of box the humid air brought into the Indian area by the south-west monsoon, with the consequence that the air is mechanically forced to ascend with copious condensation of moisture as a result of cooling by adiabatic expansion. Where the ranges obstruct the air-currents at right angles, as in the case of the Western Ghats, KL, or the Khasi Hills, HI, enormous falls of rain occur during the four or five months of the wet season. The Khasi Hills, moreover, contain a spot, Cherrapunji, so peculiarly favourable to orographic precipitation that the average annual rainfall is as high as 424 in., nearly all of which falls during the monsoon period. In the Gangetic Plains the heavy rainfall is largely due to the convergence of air-streams III., IV., V., and VII., assisted by the Himalayan wall, CD, at the base of which the forced ascent of air causes another specially wet submontane strip of country.

The dry areas in July are mostly in the "rain-shadow" of the mountains, but the desert region in the north-west of India is nearly rainless for a complexity of reasons—partly because the trend of the neighbouring mountains is not such as to force upward the comparatively small amount of air which flows into this corner of the country; partly because, with the initial conditions thus unfavourable to cloud production, what little air does arrive there from the sea is heated up so that its relative humidity is lowered and the tendency to drought consequently increased; and partly because over this part of India the upper-air current from the north-west, as revealed by direct kite observations, is warm and dry, a condition most unfavourable to condensation of moisture in any surface air that may be caused to rise. In the burning-hot Thar Desert a number of interacting factors thus conspire to maintain intense drought during what in India generally is the rainy season.

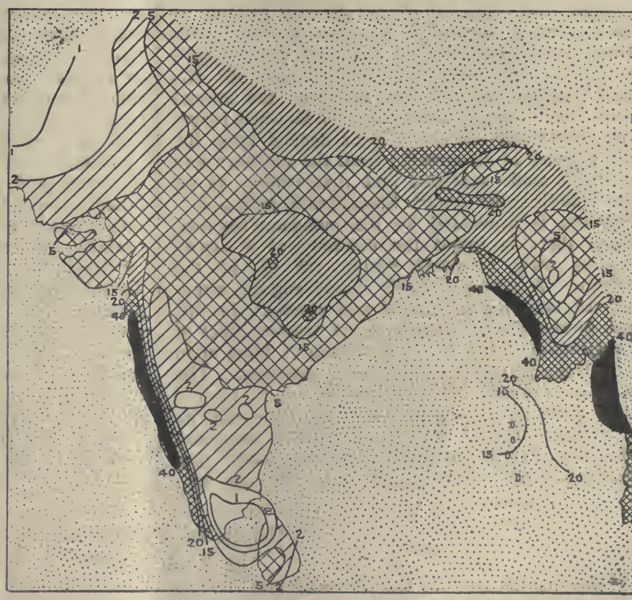

FIG. 4.—Average rainfall (in inches) of India in July.

The reason why the mountains provoke so enor-

mous a rainfall out of the monsoon current of July, and scarcely any out of the indefinite sea-winds of May, is shown by Dr. Simpson to be twofold—the July winds are both markedly stronger and damper. At Bombay, for example, the mean wind velocity is 7·4 miles per hour in May and 14·2 in July, and the relative humidity 74 and 86 per cent. respectively. Consequently, when a wind from the Arabian Sea mounts the Western Ghats, condensation will for two reasons proceed more actively in July than in May. Referring to Figs. 1 and 2, it will be seen that the pressure-gradient over India is steeper in July than in May, which means stronger winds, and that the powerful monsoon current of the former month is supplied from the south-east trade wind, with the result that the air which reaches India, after traversing some 2000 miles of sea, is necessarily very humid. In May, on the contrary, the light winds on the west coast blow somewhat north of west and conflict with the south-east trade wind over the equatorial part of the Indian Ocean, where rain falls instead of in India.

Realising how illusory charts of mean monthly meteorological conditions may be as representing actual conditions on any particular day, Dr. Simpson is able to show that the circulation in the Indian area rarely differs essentially from the mean, and that breaks in the monsoon are associated with temporary reversions to the conditions typical of May, when clear skies and fierce sunshine are broken only by violent local thunderstorms.

One cannot but support his conclusion that without the mountains the general rainfall of India would be lighter, if more evenly distributed. Those who argue that in any case the southern portion of the peninsula, below about 18° N., would experience the full effect of the annual northward swing of the equatorial rain-belt forget that the steady equatorial rains depend upon the convergence of air-streams from the northern and southern trade systems, and that where, as on the Benadir coast (Italian Somaliland), such a convergence is prevented by the monsoon regimen itself, there is found the anomaly of a nearly rainless strip of coast within 10° N. of the equator. A problem which should engage attention as facilities for travel and research in this part of the world increase is the precise effect of the Himalayas and the high plateau of Tibet upon the strength of the south-west monsoon. The effect of a broad, cold tableland 10,000 ft. high is more likely to be negative than positive—that is, to weaken rather than to strengthen the monsoon. The late Prof. Herbertson, whose insight into climatological questions was not perhaps adequately appreciated by meteorologists, used repeatedly to discountenance exaggerated notions concerning the "flue-like" action of Central Asia often entertained by those who rely too much on isothermal maps reduced to sea-level. In any case, there would be a general inflow of air towards Asia in summer, as is so well exemplified in China; but the real controlling centre of the powerful south-west monsoon of India is situated near the mouth of the Persian Gulf, and it is this "cyclonic" centre which guides the air-currents across India to the base of the Himalayas, which they must perforce mount, and thence on to the highlands of Tibet.

To summarise, the primary condition of the south-west monsoon is a centre of low barometric pressure situated to the north-west of India, due to the heated state of this region in summer, and to a certain extent of the Asiatic land-mass as a whole. The special local effect of India itself is quite subsidiary, merely serving to give the isobars and air-currents across the peninsula their final trend. In May the local heating of India, then at its maximum, does not suffice to bring about monsoonal conditions, but the general Asiatic heating in July does, for reasons discussed. A heavy rainfall accompanies the monsoon because it is both a humid and a powerful current, and is met more or less at right angles by various high mountain ranges.

Finally, it is advisable to refer to certain general principles in connection with the theory of the monsoonal circulation, the importance of which is duly emphasised by Dr. Simpson. Whilst it is a conspicuous fact that, broadly speaking, the continents command high pressure in winter and low in summer, and the oceans *vice versa*, the more detailed relationship between pressure and temperature is exceedingly complex, and the precise location of a centre of high or low pressure depends upon many other factors, such as the rotation of the earth and the configuration of the land. In other words, the atmosphere being a unity of interdependent parts, it is largely a matter of compromise, as between region and region, what type of circulation shall prevail here and what there. To take but an instance. Nothing is more perplexing than the drought-producing wind and pressure regimen of the Mediterranean basin in summer with intense insolation and active evaporation to a meteorologist who conceives of this region as isolated from other regions, and forgets that the Mediterranean circulation has to adapt itself to the great monsoon system of Asia, as well as to the conditions in other parts of the world.

Helium in Natural Gas.

By H. B. Milner.

THE researches of H. P. Cady and D. F. McFarland in 1905 on some natural gas from Kansas led to the interesting discovery of the presence of helium in that gas, a fact of which advantage was taken afterwards by the United States military authorities during the later stages of the war. In 1915 the natural gas resources of this country were investigated for a similar purpose

under the direction of the late Sir William Ramsay, and those of Canada were also examined, but in both cases the efforts were unsuccessful. The dangers attending hydrogen-filled aircraft were obvious from the fate of many of the German Zeppelins, so that the possibility of extracting sufficient quantities of an incombustible gas such as helium (admirably suited in every way to the peculiar requirements of lighter-than-air machines) was too important to be ignored.

In the United States the help of certain commercial firms, employing the Linde and Claude processes of gas liquefaction for the treatment of air, was solicited, and in 1918 two plants were in operation at Fort Worth, Texas, ultimately giving an average production of 5000 cb. ft. of gas per day, yielding on purification up to 93 per cent. of helium. Although the effect of the armistice was to check military requirements, the development of commercial aviation keeps this use of helium very much in the foreground, and in view of this and also of the far-reaching scientific problems involved the United States Geological Survey has just published, from the pen of G. Sherburne Rogers, a most valuable monograph on "Helium-bearing Natural Gas" (Professional Paper 121, 1921).

The chief region from which commercial supplies of helium are obtained is that of the Mid-Continent oilfields, more especially from two areas, one in North Texas and the other in North Oklahoma and South Kansas; gas in both these areas yielded up to 0·5 per cent. of helium, in some cases the amount being as much as 2 per cent. One would naturally expect helium-rich gas to show a high nitrogen content with consequent low calorific value; generally speaking this is found to be so, though in one instance a gas with 14 per cent. of nitrogen yielded 0·35 per cent. of helium. On the other hand, a high nitrogen content is not necessarily a criterion of a high helium yield, and Rogers cites several examples of this. The nitrogen–helium ratio in natural gas in thirteen samples quoted ranges from 114 to 20; the conclusion to be drawn from this, and also from a careful study of several other available analyses, is that a low (N_2He) ratio implies a low helium content.

The richest helium-bearing gas in America is obtained from comparatively shallow depths in the Pennsylvanian beds, and it is interesting to note that gas emanating from younger beds, such as the Cretaceous or Tertiary of Texas and Louisiana, is low in helium content. Bearing in mind Czakó's contention that the radio-activity of a gas is an index of its helium content, and also Holmes's work on radio-activity as a measurement of geological time, it is thus not difficult to appreciate the reason of the low helium content of European natural gas, derived for the most part from Tertiary strata. Evidence is not forthcoming as to the radio-activity of the gas from the Pennsylvanian beds, but McLennan's researches in Ontario (Nature, vol. 70, p. 151, 1904) demonstrated the tendency of decreased radio-activity with increased depth, and this may reasonably be correlated with the marked decrease in helium yield with increase in depth from which the gas is obtained in the present case.

The origin of the helium in the gas affords a wide ground for speculation, though in the present state of our knowledge it would be very unsafe to dogmatise. Rogers discusses this at some length, but of the several possible theories he favours two, more particularly the first—that the helium is generated from uranium or thorium deposits disseminated through the beds proximate to the natural gas horizons, or that it is primordial and comes from abyssal sources. His arguments in favour of the former theory are very sound, though, as he admits, it assumes the occurrence of radio-active deposits of which we have no knowledge, more particularly in the upper palæozoic rocks of the Mid-Continent region, or in some of the buried igneous masses occurring as subterranean uplifts.

It is interesting to note that in the case of the three principal occurrences of natural gas in this country, at Calvert, Buckinghamshire, at Middlesbrough, Durham, and at Heathfield, Sussex, the nitrogen contents were 19·5 per cent., 16·8 per cent., and 0·9 per cent. respectively; in the first case the source of the gas is doubtful, but it is presumably from pre-Liassic beds; in the second case it is obtained from the Magnesian Limestone, and at Heathfield it is unquestionably derived from the Kimmeridge Clay. If the nitrogen evaluation is any indication of helium-bearing gas, as it would seem to be in the United States, it is extremely unlikely that helium occurs in those gases in amount greater than 0·5 per cent. (if as much as that) at Calvert and Middlesbrough, while at Heathfield it is probably absent altogether.

Obituary.

Lord Bryce, O.M., F.R.S.

It can be but seldom, when a man's life has been prolonged to well over eighty years, that his death is generally felt as a serious public loss. Lord Bryce's sudden, if happy, death on January 22, in his eighty-fourth year, is a shock which will be felt equally here and in the United States, where only last summer he had been engaged both by lecturing and in social intercourse in spreading a better understanding of the problems of Great Britain and Europe. Years ago, by his great work on "The American Commonwealth," and at a later date by his tact and manifold activities while our Ambassador at Washington (he was reputed to have visited every State in the Union), Lord Bryce had made himself a living link between the two peoples. In the United States he was not only trusted by statesmen and appreciated by the leading men in thought and literature, but he was also an idol of the crowd. When he came into a popular assembly the proceed-

ings were apt to be interrupted and the whole audience would stand up and give three cheers for "good old Bryce." Among themselves the Americans to the last habitually called him "our Mr. Bryce." American citizens of all classes believed in his thorough goodwill towards their country, and he thus achieved what seemed almost the impossible in inducing them to bear kindly with criticism they felt to be both honest and friendly. For if Lord Bryce knew no better form of government than democracy, he was, as his recent work has shown, keenly alive to its imperfections and crudities both in the States and in Australia.

Politics, historical and literary studies, and travel were the main occupation of Lord Bryce's life. His career in the two former branches of activity has been fully dealt with in the general Press. Here we may more appropriately confine ourselves to the last. Lord Bryce, without being in any strict sense a man of science, though he was elected a fellow of the Royal Society, under the special rule, in 1893, took the keenest interest in several branches of natural science. His father had been a geologist, and he himself was apt to record the geological features of the countries he passed through. In botany he was an eager student, with a keen eye for rarities. In his walks near his home at Ashdown Forest he would frequently stop to recognise some relatively rare growth, and so long ago as 1859 he wrote a manual on "The Flora of the Island of Arran."

When he visited Pekin the attachés at the British Legation, who were prepared to give information on Chinese politics, were dismayed to find themselves called on to answer questions as to the local flora. In his "Impressions of South Africa" he discusses at some length the vegetation of the country, and records that he brought home fifty-four plant specimens, eleven of which were pronounced at Kew to be new to science. Wherever he went he was as keenly interested in the natural aspects and features of the country visited as in its inhabitants and their politics, and he delighted to trace the interaction between the two. His descriptive talent was exceptional, and was aided by the almost unique opportunities for comparison given him by the extent of his travels. Take at hazard this vivid sketch of Lake Titicaca:—

"The blue of Titicaca is peculiar, not deep and dark, as that of the tropical ocean, nor opaque, like the blue-green of Lake Leman, nor like that warm purple of the Ægean which Homer compares to dark red wine, but a clear, cold, crystalline blue, even as is that of the cold sky vaulted over it. Even in this blazing sunlight it had that sort of chilly glitter one sees in the crevasses of a glacier; and the wavelets sparkled like diamonds."

The shortest way to indicate the extent of Lord Bryce's travels might possibly be to give a list of the regions he had *not* visited. During the three years (1899–1901) when he was president of the Alpine Club it was noted that whatever distant range might be under discussion the ubiquitous chairman was sure to begin his remarks with, "When I was out there." I believe "The Mountains of the Moon" was one of the few places where the author of the paper had the advantage of him.

Of these many years' wanderings and holidays in a busy life (continued until last spring by a trip to Morocco) the public have had the results in three solid works. Of these, the first, "Transcaucasia and Ararat" (1877) was in the main not a mountaineering record, but a study of the Caucasian isthmus and its peoples, as seen by a passing visitor. But the account of an ascent of Mount Ararat, in which Lord Bryce reached the top without his companions, fixed public attention and had some singular consequences. In a rash moment he wrote of a piece of wood he picked up near the top, a relic of a previous Russian ascent, that he was not able to state it might not be gopherwood. When in the United States he had frequent applications from out-of-the-way local museums for the smallest fragment of this invaluable relic of Noah's Ark!

Lord Bryce's two solid volumes on South Africa and South America are, apart from their political importance, admirable pictures of the regions described. In their pages he unites the power of observation which makes a good traveller with that of generalisation which is called for in a geographer. And he carries his readers on from one topic to another by a lively style which reflects the quickness and versatility of the author's mind. Lord Bryce was engaged at the time of his death in a collection of "Memories of Travel," which we trust will be found in a state sufficiently advanced to admit of publication.

It must be added that if Lord Bryce had one hobby, or taste, stronger than another, it was for mountains and mountain climbing. He habitually found time to attend the meetings of the Alpine Club, and to take a share in its discussions. He followed the doings of its members with the keenest interest. The chief ornament of a study which was usually a chaos of proofs, letters, and presentation volumes, was a photograph of the most beautiful of snowpeaks, the Himalayan Siniolchum.

DOUGLAS W. FRESHFIELD.

SIR JOHN KIRK, G.C.M.G., K.C.B., F.R.S.

BY the death of Sir John Kirk at the advanced age of ninety, the world has lost the last survivor of the heroic pioneers of African exploration, the founder of the British position in Eastern Equatorial Africa, and a botanist whose contributions to African natural history were of first-rate importance.

Sir John Kirk was born in the Manse of Barry, near Arbroath, in 1832. He entered Edinburgh University at the age of fifteen, and obtained the degree of M.D. in 1854. In 1855 he went to Turkey with the Volunteer Medical Corps in connection with the Crimean War and served in a hospital on the Dardanelles. In 1857 he was recommended by "Woody Fibre" Balfour as physician and naturalist to Livingstone's second expedition, in which he served from 1858 until he was invalided home in 1863. On that expedition, which was the least successful of Livingstone's three, Kirk gained a higher reputation than any other of its members. His unfailing good humour, tact, and great gift of

sympathy must have been invaluable, and in spite of internal dissensions in that expedition, Livingstone afterwards wrote that he had never had any difference with Kirk. Livingstone has borne warm testimony to Kirk's untiring zeal, energy, and courage. He collected 4000 species of plants, in addition to zoological specimens, making careful studies of the economic products. In gratitude for his help Livingstone named the western wall of the Rift Valley along the Shire River and Lake Nyasa, the Kirk Range.

Kirk returned to East Africa in 1866 as physician to the Consulate at Zanzibar. He was fortunately soon entrusted with political work, and became Vice-Consul in 1867 and Consul in 1873. In 1870 Said Barghash succeeded to the Sultanate, and the general impression of his character is summed up in Kipling's "from Said Barghash in a tantrum," but he was never in that condition with Kirk. Both men had a keen sense of humour, and Kirk soon gained an immense influence over Said Barghash, who was a loyal friend. When the Sultan was visiting this country in 1875 he threatened to return at once because he felt that Kirk had been treated rudely by the Duke of Cambridge. In 1873 the combined influence of Sir Bartle Frere's mission and of Sir John Kirk secured the abolition of the slave trade in the Dominion of Zanzibar. Sir Frederick Lugard has testified to the efficiency with which Kirk ensured the enforcement of that edict by the Slave Court at Zanzibar, while insisting on the missionaries taking no illegal premature steps in reference to domestic slavery. In 1877 the Sultan offered a British syndicate a lease of his dominion on the mainland; but the British Government would not accept the offer, and it was not until after Germany had secured the southern part of those territories that a concession of the rest was accepted, and the British East Africa Company founded to administer them. Kirk was one of the founders and original directors to whom the Royal Charter of that company was awarded. Its ultimate failure was one of his most bitter disappointments. The company was incorporated in 1888, and Sir John Kirk thenceforward lived in England. He served for many years as foreign secretary of the Geographical Society, which gave him its Patron's Medal in 1882. He was elected fellow of the Royal Society in 1887; he was also a D.C.L. of Oxford and Sc.D. of Cambridge.

Kirk's scientific work was mainly botanical. He was a most indefatigable collector; he described some of his new plants, and wrote many articles for the *Kew Bulletin* and other scientific journals. His collections have greatly enriched the Kew Herbarium, and have been described as amongst the most important materials for its "Flora of Tropical Africa." His main interest was in economic botany. He established at his own expense at Mbweni, near Zanzibar, an experimental plantation of which the results were of the highest value, and introduced many trees and plants, and some of the extensive eucalyptus plantations in East Africa came from seeds raised from his trees. He wrote reports on olive culture and on fibres, one of the valuable local supplies of which comes from *Sansevieria Kirkii*.

Kirk founded the East African trade in wild rubber, the best of which came from *Landolphia Kirkii*, and his name is also commemorated in many other important East African plants. He introduced through Kew a considerable series of new plants to British gardens.

After his return to this country he was regarded, until blindness lessened his usefulness, as one of the most trustworthy referees from the Foreign Office on African questions. In 1889–90 he was a plenipotentiary to the Brussels Conference, and for his services there was made K.C.B. His K.C.M.G. was awarded in 1881, and his G.C.M.G. in 1886. He was Vice-Chairman of the Uganda Railway Committee, and was sent to Nigeria to inquire into the famous case of sacrificial cannibalism when forty prisoners were eaten at Akassa.

The beautiful little antelope, "Kirk's Gazelle" (*Madoqua Kirkii*), will help to preserve his memory among settlers in the lands he secured to the Empire. To the explorers of that area Kirk was a friend who will always be remembered with most sincere affection and respect.

Prof. J. H. Cotterill, F.R.S.

On January 8 Prof. James Henry Cotterill died at Parkstone, near Bournemouth. Prof. Cotterill was the youngest son of the Rev. Joseph Cotterill, of Blakeney, Norfolk. Educated at Brighton College, he was afterwards apprenticed in the works of Sir William Fairbairn, at Manchester. Later he went to St. John's College, Cambridge, and took a fair place in the mathematical tripos. In 1866 he became lecturer and in 1870 vice-principal at the Royal School of Naval Architecture and Marine Engineering at South Kensington. In 1873 the school was moved to Greenwich, and became part of the Royal Naval College, in which Prof. Cotterill was professor of applied mathematics until his retirement in 1897. He was elected hon. vice-president of the Institution of Naval Architects in 1905.

In 1806 a commission had recorded the opinion that the highest officers then responsible for the design and construction of vessels of the Royal Navy were sadly ignorant of the theory of naval architecture, and, in fact, in the early nineteenth century the best ships in the Navy were those captured or copied from the French. In 1811 the first Admiralty School of Naval Architecture was opened at Portsmouth for training expert advisers, under Dr. Inman. It lasted twenty years, but trained only forty students, some of whom, like Isaac Watts, chief constructor, attained distinction. In 1848 a second school was opened at Portsmouth, under the principalship of the Rev. Dr. Woolley, and entry from the dockyard schools was made dependent on merit. It lasted only five years. Mr. E. J. Reed (chief constructor) and Mr. Barnaby (chief naval architect) were among its students on whom devolved the responsibility of the transition to ironclad construction. Chiefly at the instance of the Institution of Naval Architects, the third Admiralty school was

established at South Kensington, and this continues its good work as part of the Royal Naval College.

This institution had the great advantage that the Admiralty students from the dockyard schools were well prepared for advanced instruction. It has, through the distinguished careers of many of its students, exercised an important influence on the shipbuilding industry in this country, and on the development of the great Navy which commanded the seas in the late war. The organisation of the theoretical part of the instruction was mainly due to the ability, industry, and originality of Prof. Cotterill. An account of the courses of study is given in the later editions of his "Applied Mechanics." The school was open to private students, and some of these obtained important positions in private shipyards and in the constructive departments of foreign navies.

Prof. Cotterill's earliest papers were on least action, on the theory of propellers, and on the reaction of an elastic fluid escaping from an orifice. In 1878 he published a treatise on "The Steam Engine considered as a Thermodynamic Machine"; and in 1884, a treatise on "Applied Mechanics." Both these have passed through several editions, are still in use, and have much influenced the teaching of the subjects in engineering schools in this country and in America.

WE record with much regret the death on January 22, at seventy-six years of age, of Sir William Christie, K.C.B., F.R.S., Astronomer-Royal from 1881 to 1910.

Notes.

IN a letter to the *Times* of January 23 Mr. F. P. Mennell recalls his description of the bone-cave at Broken Hill, Rhodesia, published in the *Geological Magazine* in 1907, and adds some further details in reference to the recent discovery of *Homo rhodesiensis* in a deeper extension of the cave. He emphasises the fact that all the stone and bone implements found with this extinct cave man are such as are used to-day by the Bushmen and Hottentots in outlying places, while all the mammalian bones, evidently broken for food, belong either to living species or to species closely allied to those still existing in the neighbourhood. The Rhodesian man is therefore probably not so old as the primitive types of man who wielded the Palæolithic implement in western Europe. We may add that Mr. Mennell's original paper was referred to in NATURE of November 17 last by Dr. Smith Woodward, who also expressed the opinion that Rhodesian man would prove to be of comparatively recent date.

IT was resolved by the General Committee of Subscribers to the Rayleigh Memorial, after arranging for the erection of the tablet in Westminster Abbey, which was unveiled recently, "that the executive committee be empowered to use the balance for the establishment of a library fund at the Cavendish Laboratory." The amount subscribed to the memorial fund was 1575*l.*, and after defraying all expenses connected with the tablet the balance was 687*l.* 15*s.* 8*d.* In accordance with the resolution of the general committee, Sir Richard Glazebrook and Sir Arthur Schuster, secretaries of the fund, have now sent a cheque for this amount to the Vice-Chancellor of the University of Cambridge. The committee desires that of this sum 600*l.* should be treated as capital, the interest upon which is to be at the disposal of the Cavendish professor annually for the purposes of the library; the balance of the capital, namely, 87*l.* 15*s.* 8*d.*, may be drawn upon at once in order to bring the library up to date. It is suggested that a book-plate should be prepared connecting the books purchased out of the fund with Lord Rayleigh.

THE Père Lachaise cemetery in Paris, which has during the last few days witnessed several acts of homage to the memory of the great dramatist Molière, contains a large number of tombs and monuments of remarkable interest. Among these are many to the men of science of last century. The cemetery was laid out in 1804, and the monument to Molière was one of the first erected in it. Walking round the paths familiar names of statesmen, poets, musicians, writers, soldiers, and painters catch the eye at every turn. Science is represented by the mathematicians Poinsot, Monge, Hachette, and Charles; the astronomers Arago and Delambre; and the chemists Dulong, Gay Lussac, Chaptal, Boussingault, and Raspail. Comte, Cuvier, Bichat, Claude Bernard, and Geoffrey St. Hilaire are also commemorated. Quite close together will be found the tombs of Madame Lavoisier who made such an unhappy alliance with Rumford, and Madame Blanchard, the intrepid aeronaut who perished in 1819. Other pioneers in the conquest of the air whose names are perpetuated in the cemetery are Robertson, Charles, Croce-Spinelli, Gaston, and Tissandier.

FROM the *Daily Telegraph* we learn that the Paris Academy of Sciences has received an invitation, through Prof. Kriloff, a specialist in naval construction, to send representatives to Moscow to the celebration of the bicentenary of the Russian Academy of Sciences, to be held in 1925. Prof. Kriloff, in his speech, expressed the hope that science would throw solid bridges over the chasms made by war, and that the relations of all the peoples would be re-established with the same cordiality as before. The initiation of the Russian Imperial Academy of Sciences was due to Peter the Great, though its actual inauguration was carried out by his widow, Catherine I. It was she who invited the great mathematician, Leonhard Euler, to her capital, but her death occurred on the day Euler set foot on Russian soil. Joined by Daniel Bernoulli and the astronomer Delisle, Euler continued to work at Petrograd until 1741. His surroundings, however, were not always

congenial, and afterwards when a princess at the Court in Berlin asked him why he spoke so little, he replied: "Madame, parce que je viens d'un pays où quand on parle on est perdu." Euler continued to send memoirs to the Academy, and in 1766 he accepted the invitation of Catherine II. to return to Petrograd, and he died there in September, 1783. Some of his sons entered the Russian service, while his son-in-law, Nicolas von Fuss, became permanent secretary to the Academy.

ONE of the largest telescopes in the world, hitherto unused, is likely to be brought into service shortly, according to an announcement made at a recent meeting of the American Astronomical Society. It is a 60-in. reflector constructed by the late Dr. A. A. Common about thirty years ago and bought by the Harvard Observatory in 1902. It is exceeded in size by two telescopes only, both of them on the Pacific coast—the 100-in. reflector at Mount Wilson, in California, and the 72-in. reflector, the property of the Dominion Government, at Victoria, in British Columbia. A second reflector at Mount Wilson is of the same size as that at Harvard. The Harvard instrument was purchased for visual and photographic star measurements, but when set up and tested was found unsatisfactory for that purpose. It was therefore abandoned, and has ever since been stored away in the observatory grounds. Meanwhile, the science of astrophysics has provided an increasingly large number of problems, in which the light and heat from a star, rather than the size of a photographic image, are the things measured. It is for such problems as these that the Harvard telescope, with its 5-ft. mirror—once considered useless because it would not produce perfect images—is now to be employed.

AT the annual general meeting of the Royal Society of Arts, on June 30, 1920, it was announced that unless the society succeeded in purchasing the freehold of its house in John Street, Adelphi, it would be obliged to find new quarters after March, 1922. The matter was referred to again in the annual meeting on June 29 last, and the sum of 50,000*l*. was mentioned as the cost of buying and renovating the property. An appeal for subscriptions was therefore made in order to obtain funds to secure permanent possession of the historic house built for the society by the brothers Adam about 1775. So far, two lists of subscribers have been issued in the society's journal, from which it appears that the sum of 40,678*l*. has already been raised. Of this total no less than 30,000*l*. is due to the generosity of one anonymous benefactor. Other noteworthy subscriptions are 2,500*l*. from Sir Charles A. Parsons, and 1000*l*. each from Lord Bearsted, Sir Dugald Clerk, the Earl of Iveagh, Lord Leverhulme, and Mr. A. A. Campbell Swinton. The sum already subscribed should be sufficient to secure the continuity of tenure of the John Street house, which has been the scene of the society's labours for the past 147 years, but it is to be hoped that further contributions will be forthcoming, so that the whole of the purchase-money may be available, and also means for making desirable alterations in the meeting-room and other parts of the building.

AT the annual general meeting of the Royal Meteorological Society on January 18 the Symons gold medal, which is awarded biennially for distinguished work in connection with meteorological science, was presented to Col. H. G. Lyons. Dr. Charles Chree was elected president of the society for the year 1922.

DR. G. CLARIDGE DRUCE has recently been elected a corresponding member of the Botanical Society of Czecho-Slovakia "for his inestimable services to botanical science." The diploma is signed by the president of the society, Prof. Karel Domin, professor of systematic botany in the University of Prague.

ON Tuesday next, January 31, Prof. H. H. Turner begins a course of three lectures at the Royal Institution on "Variable Stars," and on Thursday, February 2, Sir Napier Shaw delivers the first of two lectures on "Droughts and Floods." The Friday evening discourse on February 3 will be delivered by Sir Francis Younghusband on "The Mount Everest Expedition," and on February 10 by Dr. Halliburton on "The Teeth of the Nation."

THE Civil Service Commissioners announce that an open competitive examination for not fewer than fifteen situations as assistant engineer in the Engineer-in-Chief's Department of the General Post Office will be held in London, Edinburgh, and Manchester in April next, commencing on April 20. The limits of age are twenty and twenty-five, with certain extensions. Regulations and forms of application will be sent in response to requests by letter addressed to the Secretary, Civil Service Commission, Burlington Gardens, London, W.1.

HAVING regard to the confusion which now exists, especially in overseas trade, due to the difference between the American gallon and the Imperial gallon, the Decimal Association urges that it is desirable for an agreement to be reached between the Governments of Great Britain and the United States to the effect that as an alternative to either of the above gallons being adopted by both countries as a common standard, each of them should forthwith adopt the litre, which could be described as the "metric gallon." It is obvious that uniformity of practice in a matter of this kind is most desirable, and the adoption of the metric gallon would not only standardise practice between Great Britain and America, but also with practically all other countries engaged in international trade.

A PORTRAIT of Sir Patrick Manson was unveiled by Sir James Michelli at the London School of Tropical Medicine on January 20. The portrait was subscribed for by a large number of past and present students and other friends at home and abroad. The painting was entrusted to Mr. E. Webster, and is a most pleasing likeness. It hangs in the vestibule of the school, where it will be seen by the large number of students attending the classes. Reproductions of the

portrait will be made by Mr. Malcolm Osborne, and will soon be ready for distribution. In recognition of Sir Patrick Manson's services as a clinician, money has also been subscribed for a medal, which will be awarded annually to those who distinguish themselves in clinical work. The medal will bear a portrait of Sir Patrick Manson by Mr. John Pinches.

THE programme for the Air Conference to be held at the Guildhall on February 7–8 has now been issued. During the morning of the first day of the meeting papers will be read by Lord Gorell on civil aviation, and Lt.-Col. W. A. Bristow on aerial transport of to-day and to-morrow. Papers on research work from the points of view of designers, constructors, and users by Major F. M. Green, on the progress of research by Brig.-Gen. R. K. Bagnall-Wild, and on airships by Major G. H. Scott will occupy the afternoon session. The whole of the second day of the meeting will be devoted to general discussions. In the morning Capt. F. E. Guest will preside, and civil aviation papers read during the previous morning will be dealt with; in the afternoon the chair will be taken by Lord Weir of Eastwood, and the technical papers of the previous afternoon will be discussed.

INFLUENZA had materially increased in severity, according to the Registrar-General's return for the week ending January 14. Deaths due to the epidemic numbered 1240 for the ninety-six great towns of England and Wales, an increase of 433 on the preceding week. In London the deaths were 551 for the week, an increase of 197 on the preceding week. During the great epidemic of 1918–19 the deaths from influenza in London amounted to 2458 in the week ending November 2 and to 2433 in the week ending November 9, but with the exception of the 1918–19 epidemic the death-rate is now higher than in any other epidemic of influenza since 1890, the nearest approach occurring in the epidemic of 1892, when for the week ending January 23 the deaths in London numbered 506. During the week ending January 14 the deaths between the ages of sixty-five and seventy-five were 21 per cent. of the total. Deaths from pneumonia and bronchitis have also considerably increased.

A SUMMARY of weather results for 1921 is given in the *Weekly Weather Report* of the Meteorological Office for the closing week of December, showing the mean and aggregate values for the several districts of the British Isles. There was a general deficiency of rain, the only districts with an excess being the north and west of Scotland, these districts having respectively 106 and 104 per cent. of the average fall. In the east of Scotland the rainfall for the year was 87 per cent. of the average, and in the north of Ireland 89 per cent., whilst in the north-west of England it was 86 per cent. In the north-east of England the rainfall was 73 per cent. of the average, and in the Midland Counties 69 per cent. The rainfall was only 48 per cent. of the average in the east of England, followed by 50 per cent. in the south-east of England, 54 per cent. in the English Channel district, and 60 per cent. in the south-west of England. The district having the largest amount of rain during the year was the north of Scotland with 54·34 in., while in the east of England the total measurement was 13·45 in., and in the south-east of England 13·84 in. The mean temperature for the year was above the normal in all districts; the greatest excess was 2·7° F. in the English Channel district and 2·5° F. in the north-east and east of England and the Midland Counties. The duration of bright sunshine was in excess of the average in all districts over Great Britain; the greatest excess was 0·7 hour per day, amounting to 250 hours for the year in the east of England and 0·6 hour per day in the Midland Counties and the south-east of England.

THE problem of the conservation of the coal resources of Great Britain involves the study and classification of the coal seams which are at present being worked or developed, and also of seams above or below ground which are being left unworked or are thrown aside. On its directly practical side this work must deal primarily with the suitability of each particular coal for those purposes for which its individual qualities render it most appropriate, and the Fuel Research Board believes that the most effective way of achieving this end is by the co-operation in local committees of colliery owners, managers, and consumers with the representatives of the Fuel Research Board and the Geological Survey. By this combination local knowledge and experience, as well as the initiative of those most deeply interested in the practical aspects of the survey, will be secured. Thus from the outset the survey will assume a practical character. The selected seams will be submitted to physical and chemical examination by the local experts, and as a result of this examination a further selection will be made of those which appear to justify experiments on a practical scale to test their suitability for particular uses or methods of treatment. This experimental work will be carried out either at H.M. Fuel Research Station or at other works, as may be found most convenient. A start has already been made in the Lancashire and Cheshire district, where the local research association has been recognised by the Fuel Research Board as its representative body for the purpose of dealing with the physical and chemical survey of the coal seams in this area. The chairman of the new committee is Mr. R. Burrows, and the director of research Mr. F. S. Sinnatt.

A LEADING article in the *Museums Journal* for December suggests as a remedy for the alleged overcrowding of the national museums that their redundant specimens should be transferred to the provincial museums, and asks for a Commission to consider the limits of our national museums and how far it is possible for them to assist the provincial and "Colonial" museums. In the January issue Mr. Williamson, of the Derby Museum, while admitting past help, would welcome gifts or long loans on a more systematic plan and with more reference to local

needs. Dr. F. A. Bather, while in agreement with the proposal, maintains that such transference is the policy of the British Museum, which is only prevented from carrying it out fully by inadequacy of staff. He also points out that the interests of scientific students demand the accumulation of large collections in as few centres as possible, and that the bulk of such material is not really redundant. Sir Frederick Kenyon in his presidential address to the Museums Association in July last expressed a wish to meet the needs of provincial museums if they would make them known.

DR. RAPHAEL KARSTEN, lecturer in the University of Helsingfors, Finland, has made an important contribution to anthropology in the first part of his "Studies in South American Anthropology." He deals more particularly with personal ornamentation, ceremonial mutilation, and kindred customs. The savage man's love for self-decoration has been discussed by many anthropologists. Darwin believed that the object of these decorations was to make man beautiful, and especially attractive to the other sex; W. Joest, while admitting that body-painting has a practical value in protecting the body from insects, heat, or cold, admits that the principal motive, besides inspiring enemies with fear in battle, is sexual desire, a view generally accepted by Westermarck in his "History of Human Marriage." Dr. Karsten believes that the part which magic has played in originating primitive customs has, up to recent times, been much underrated, owing to our defective knowledge of the psychology of savage man. This side of the subject is pursued in this monograph, which, though principally devoted to South America, discusses the question from other points of view, and, with its careful citation of authorities, deserves the attention of anthropologists.

NATIONAL laboratories for the cleaning, restoration, and preservation of antiquities have for some years existed at Berlin, Copenhagen, and Stockholm. Well-known books on the subject have been published by Dr. Rathgen (ed. 2, 1914) and Dr. Rosenberg (1917), the latter dealing with iron and bronze objects only. In our own country there was no laboratory for the purpose until 1920, when Dr. Alexander Scott was induced by the Department of Scientific and Industrial Research to direct the work of a small laboratory temporarily equipped at the British Museum (Bloomsbury). So far as the English language was concerned, G. A. and H. A. Auden's translation of Rathgen's first edition (1905), a chapter in Prof. Flinders Petrie's "Methods and Aims in Archæology" (1904), and a few articles in the *Museums Journal*, notably a well-illustrated one by Dr. Rathgen (1913), were about all the museum curator had to guide him. Now the Department just mentioned has issued a first report by Dr. Scott (Bulletin No. 5, 1921, 2*s*.). It deals with prints, enamels, silver, lead, iron, copper and copper alloys, and rock-paintings. Dr. Scott has attacked the problems *de novo*, and has evolved some new and ingenious methods. Their success is illustrated by some photographs "before" and "after."

A VERY complete summary on the subject of anthrax infection in man appears in the Bulletin Mensuel for November last of the Office International d'Hygiène Publique, Paris (t. 13, No. 11, 1921, pp. 1135–1239). Anthrax infection in man is most commonly seen as a cutaneous manifestion, the characteristic malignant pustule, which is caused by local inoculation. Internal anthrax also occurs in the lungs, intestine, and brain, and is caused by inhaling or swallowing the spores of the anthrax bacillus. Internal anthrax is always fatal, but the malignant pustule is fairly amenable to treatment, if taken in time, by anthrax serum or by excision. The disease is always transmitted from an affected animal, living or dead, or from the commercial products derived from an affected animal, such as skins and hides, goat, camel, or horse hair, and wool. Between 1915 and 1920 a number of cases of human anthrax due to shaving-brushes has been reported in England (49), United States (40), Holland, Italy, and Egypt, the brushes having been made with infected hair. In Holland few cases of human anthrax occur, less than a dozen per annum. The same is the case in Norway, in spite of the frequent occurrence of the disease in domestic animals, though among these the frequency of the disease is diminishing, from 686 animals affected in 1906 to 33 in 1920.

THE last report of the Grain Pests (War) Committee established by the Royal Society has now made its appearance. It required the conflagration of a European war and the threat of starvation to Britain to stir us to investigate some of the problems connected with the destruction of grain by insects. Though the committee set up by the Royal Society was purely a war one, it seems a pity that it should cease to act just when the fringe of the subject has been touched. Could the Royal Society not be induced to continue the investigations? The present report (No. 9) contains a short note by Prof. Goodrich on the parasitisation of certain grain beetles by Hymenoptera. It is shown that these parasites are not likely to prove of value as a means of controlling the beetles, as the chalcids are themselves kept in check by carnivorous acarids. The second part is by Dr. J. Waterston, who deals with the systematics of the parasitic Hymenoptera. These parasites are, like their hosts, cosmopolitan, and many of the species previously described were certain to fall as synonyms. This comprehensive and beautifully illustrated paper should prove the basis of future work. The last report is that by Mr. J. H. Durrant on the species of insects found in grain; hundreds of samples of grain were examined from different parts of the world. These are all tabulated, showing the species found in each. We note that several species of beetles are new to our lists of grain pests. Altogether, much useful information is contained in the report.

IN the November issue of the Journal of the Franklin Institute Dr. Carl Hering brings together some of the phenomena produced by the flow of heavy currents in conductors which have been observed in recent times, and points out that in

many cases they violate some of the laws of electromagnetism as stated in current text-books. He therefore pleads for a restatement of these laws in such form that there shall be no apparent exceptions to them. In the first instance, he points out that it is not sufficient for the production of electromotive force by magnetic induction that lines of magnetic force shall cut through a *circuit*, but that the lines must cut through a *conductor*. Further, he contends that the existence of the "pinch" effect, contracting the section of a conductor carrying current, of the "stretch" effect, lengthening the conductor, and of what he has named the "corner" effect, when a conductor changes its direction, render it advisable to modify the dictum that the forces on a conductor "can never have a resultant in the direction of the axis."

THE firm of Messrs. Barr and Stroud, which grew out of the remarkable inventive work of the partners, was from 1888 until 1918 mainly occupied with the manufacture of range-finders and other instruments relating to the gunnery requirements of many different countries. They have since turned their attention also to the small type of internal-combustion engine used on motor-cycles, and, as a consequence, have now put on the market an engine of 349 c.c. capacity working on the four-stroke cycle and having a sleeve-valve and air-cooling. The engine is made under the well-known Burt and McCollum patents and has several attractive features. The absence of all external valve mechanism makes for cleanliness and greatly lessens engine noise. It is a light engine, since its weight to horse-power ratio is, it appears, but 7 lb. per h.p. when giving the maximum power of 7 h.p. The sleeve has a double motion, both horizontal and vertical, so combined that any point in it moves in an elliptical orbit. It has five curiously shaped ports, two for inlet, two for exhaust, and one for the double purpose, serving each in turn. The general design is very attractive, and the claim for a special degree of ease in dismantling and adjusting appears to be substantiated by an examination of the details of the design. Tests on the road have shown a satisfactory degree of fuel economy.

DURING the past forty years many proposals have been considered by the authorities in New South Wales for providing suitable means of communication across Sydney Harbour to accommodate the growth and development of Sydney. Tenders and designs have now been invited for the construction and erection of a cantilever bridge. Some particulars of this project are given in an illustrated article in *Engineering* for December 30 last. The bridge will carry four lines of railway, a main roadway 35 ft. wide, a motor roadway 18 ft. wide, and a footway 15 ft. wide. The total length, including the approach spans, will be 3816 ft.; the headway required for shipping will be 170 ft. at high water for the central 600 ft. of the bridge. The bridge is to consist of steel cantilevers with shore and harbour arms each 500 ft. long and a central suspended span of 600 ft. The clear span from centre to centre of the main piers will be 1600 ft. For the information of tenderers a number of interesting tables is given, showing the range of temperatures and intensities of prevailing winds and the extreme velocities and pressures recorded during the severest storms in Sydney. Full particulars are also given regarding the loads to be employed in estimating and the stresses to be used. The specification has been prepared by the chief engineer, Mr. J. J. C. Bradfield.

THE council of the Chemical Society has issued a pamphlet of eleven pages dealing with the furnishing and equipment (so far as fixed fittings are concerned) of chemical laboratories as the result of a conference of various bodies interested called by the society eighteen months ago at, we believe, the suggestion of the Royal Institute of British Architects, though this is not mentioned. The object in view was to ascertain whether, in view of the high prices of labour and materials, economies could be effected in laboratory fittings. A small committee of the society was appointed and decided to investigate present practice, and the report gives information collected from various institutions. Though necessarily but a slight contribution to a very large subject, the report contains a useful epitome of the methods in use for forming and treating bench-tops, reagent shelves, fume cupboards, sinks, and waste channels, while notes on ventilation, supply services and floor and wall surfaces are added. Finally, a short bibliography is given on the subject of laboratories, upon which, however, there is very little literature. Laboratory fittings are always costly, and at the present time, when so much educational work is held up owing to lack of funds for its material development, any information which will enable those responsible for designing laboratory fittings to cheapen and simplify requirements is bound to be of service. As regards the use of wood particularly, it seems much to be desired that experiments be undertaken in order to ascertain whether many of the cheaper soft woods cannot, by impregnation or other suitable treatment, be made to serve in place of imported hard woods.

THE August issue of the Journal of the American Chemical Society contains an account of the separation of the isotopes of chlorine by diffusion, contributed by W. D. Harkins and A. Hayes. The work was begun in 1915, and has been carried out in the chemical laboratories of the University of Chicago. A preliminary account of the separation of a heavier fraction from hydrogen chloride by diffusion through the stems of tobacco-pipes was given in NATURE of April 22, 1920, p. 230. Calculations by Rayleigh's formula show that to produce an increase of 0·2 in the atomic weight would require the diffusion of 130 tons of hydrogen chloride gas. The relative amounts of the different isotopes are as important as the atomic weight differences, and it is shown that, contrary to what has been supposed, it is easier to produce a small increase in the atomic weight of chlorine than to produce the same increase in the atomic weight of neon. The diffusion was carried out through clay pipe-stems or tubes at atmospheric pressure. Low pressures would be more advantageous. The increase

in atomic weight amounted in different experiments to from slightly less than to considerably more than one part in a thousand. A considerable amount of the isotopic acid has been produced. These experiments seem to confirm beyond doubt the existence of the isotopes of chlorine first announced by Dr. Aston on the basis of positive-ray analysis. The latter method gives, in addition, the atomic weights of the two isotopes.

MESSRS. BENN BROS., LTD., announce for publication in March a work which should be of interest and value to many readers, viz. "The Early Ceramic Wares of China," by A. L. Hetherington, in which will be described the main characteristics of the products of the Chinese factories before 1368. The same publishers also promise a new series entitled "The Chemical Engineering Library," the first nine volumes of which will be The General Principles of Chemical Engineering Design; The Layout of Chemical Works, H. Griffiths; Materials of Construction: I., Non-Metals, H. Griffiths; Materials of Construction: II., Metals, H. Griffiths; Mechanical Handling, A. Reid; Weighing and Measuring Chemical Products, Malan and Robinson; Flow of Liquid Chemicals in Pipes, N. Swindin; Chemical Works Pumping, N. Swindin; and Factory Wastes as Fuels, A. Reid.

MESSRS. H. K. LEWIS AND CO., LTD., 136 Gower Street, London, have just issued an up-to-date list of "College Text-books and Works of Reference in Science and Technology." The titles are arranged under authors' names, and are classified under eighteen subjects, some of which, such as chemistry, engineering, etc., are again divided. The subjects are arranged alphabetically, whilst a contents-list on the first pages makes reference to any subject quick and easy. The list will be sent post free to any address on application.

Our Astronomical Column.

DEDUCTION OF STAR-DISTANCES FROM PROPER MOTIONS.—The proper motions are almost our sole guides in estimating the distances of the more remote stars. Hence any method that affords a check on the results is of value. Prof. H. N. Russell points out in the *Astrophysical Journal* for September last that we can estimate the distance either (1) by correlating the motion away from the solar apex with the sun's velocity, or (2) by correlating the cross-motion with the line-of-sight velocity. As a test he has divided the 180 stars of type B_0 to B_5, the radial velocities of which were found by Campbell, into eighteen groups, the mean position of each group being nearly the same. He finds for the general mean parallax 0·0083″ from (1) and 0·0058″ from (2). One reason given for the smaller value from method (2) is that some of the stars may be undetected spectroscopic binaries, in which case the adopted line-of-sight velocity is presumably too great. The probable error of result (1) is 0·0010″, of (2) 0·0014″. In general, method (1) gives the best results for objects of small average velocity like the B stars, while (2) is better for quick movers like the planetary nebulæ. The apparent close connection between period and absolute magnitude in the Cepheid variables was originally deduced from results obtained by method (1), and later obtained considerable confirmation from a study of the variables in the globular clusters, which appear to be mainly Cepheids.

METEORIC SHOWER OF DECEMBER 4–5, 1921.—Mr. W. F. Denning writes that he has received a communication from the Tokyo Astronomical Observatory, Japan, stating that an abundant display of meteors was observed there on the morning of December 5. Watching 55 minutes between 4.15 and 5.10 G.S.T. of Japan (December 4 between 7.15 and 8.10 G.M.T.), Mr. S. Inouye saw fifty or sixty meteors, and recorded the paths of forty-six meteors, among which forty-four radiated from about $156°+37°$ near β Leonis Minoris. The meteors were rather rapid, and the magnitudes ranged nearly from 2·0 to 4·5.

On the next morning Mr. Inouye watched 15 minutes, but no meteors belonging to the same radiant were observed.

Mr. S. Kanda calculated the following elements from the above radiant point, assuming the orbit to be parabolic:

$$\Omega=252{\cdot}1°,\ \omega=232{\cdot}6°,\ i=133{\cdot}3°,\ q=0{\cdot}791.$$

No comet is identified with these elements.

Mr. Denning adds that this shower in Leo Minor was well observed at Bristol on November 25–28, 1876, when he observed 26 meteors from the point $155°+36°$. The observation was reported in NATURE of December 21, 1876, p. 158. The shower was also seen by him on December 2, 5, 7, and 10, 1885, when the radiant point was redetermined at $152°+40°$.

The display witnessed at Tokyo on the night following December 4 last could scarcely have been well observed in England, for when the maximum occurred at 7.35 p.m. G.M.T. the radiant point was close to the north-north-east horizon, whereas at Tokyo it was situated only a few degrees east of the zenith, and splendidly placed for the abundant distribution of its meteors.

POPULAR ASTRONOMY IN SWEDEN.—The Stockholm periodical *Populär Astronomisk Tidskrift* continues to produce articles of much interest and practical value. Häfte 3 and 4, 1921, contain a useful illustrated article by Edv. Jäderin on the graphical prediction of eclipses and occultations. The methods are easy to follow and capable of an accuracy that is amply sufficient.

O. A. Åkesson discusses the periodicity and motion of sun-spots. The daily amounts of rotation for different latitudes are plotted for the two periods 1886–97 and 1898–1909. The values for the second period show a diminution of nearly 1 per cent. compared with the former. H. v. Zeipel contributes a study of the cluster M 37, near θ Aurigæ. He finds the colour-indices by comparison of photographic with photo-visual magnitudes, and deduces a distance of 1500 parsecs. There is also an illustrated article on the Babelsberg Observatory and its new refractor (aperture 65 cm.) and reflector (aperture 120 cm.), both made by Zeiss.

The approaching series of occultations of Aldebaran are the subject of a useful note. Accurate observations of the bright-limb phases of these phenomena will serve to test the conjecture that there may be a sensible atmosphere on the moon's sunlit face.

Physiology at the British Association.

THE outstanding features of this most successful meeting at Edinburgh were the large number of discussions and the giving of an official semi-popular lecture. Before the beginning of the latter a very pleasant interlude was furnished by Prof. Halliburton announcing a presentation to Sir Edward Sharpey Schafer on his seventieth birthday by his former students and co-workers.

The address of the president of the section was followed by a debate. Sir E. Sharpey Schafer discussed three points in connection with physiology, namely, the position of histology, physiology as a pure science, and physiology in relation to clinical medicine. He stated that anatomy is not a dead subject without histology, as it can be developed along the lines of morphology and embryology, but that histology is essential for the proper understanding of physiology. He further pointed out that, although it can be called microscopic anatomy, histology has developed as a branch of physiology. The study of physiology as a pure science is necessary, because it is in the pursuit of knowledge that discoveries are made. It is not always known what practical applications may arise for new knowledge, but by confining one's attention to purely practical applications the reserve of knowledge to be applied will become exhausted. The application of physiology to clinical medicine should come by the clinical teacher having held a position in the physiological laboratory. The physiologist has sufficient work to accomplish in his laboratory without attempting to become a clinician. By the proper training of clinical teachers in physiology it is hoped that invaluable applications will arise in medical practice.

A number of other speakers took part, all of whom enforced the views of Sir Walter Fletcher that physiology must be studied as a pure science in a university; that the physiologist should study the organism as a whole, so that histology, chemistry, and physics all may be applied to explain the behaviour of living organisms; and that it is only by a combination of all these that one can appreciate to what extent the chemical and physical processes may be regulated in the living cells.

Prof. A. R. Cushny opened a discussion on the relation of tests for studying the efficiency of the kidney to the views as to the function of the kidney. Various tests have been used to test the functional activity of the kidneys without a proper consideration of the conditions of its activity. The excretable substances must be distinguished from the non-excretable. The threshold substances are those which are excreted when their concentration rises above a certain threshold, and the no-threshold substances are those which are completely excreted, *i.e.* they are of no further use to the organism. Of the various substances used, water, chlorides, and urea are not satisfactory, as they are not completely excreted. By comparing the amount of urea and sulphate in blood and urine it has been found that sulphate is concentrated twice as much as urea, so that the functional activity as judged by the sulphate excretion would be twice as great as when judged by the urea excretion. Sulphate, phosphate, and creatinine were concentrated to equal degrees; therefore, the concentration of any of these in plasma and in urine might be measured as a test for functional activity.

Prof. J. Meakins commenced by agreeing that urea is not a toxic substance. He quoted cases where chronic incomplete obstruction of the ureter gave rise to a large volume of dilute urine. If temporary removal of the obstruction causes the kidney function to become normal, this is an indication for surgical interference; but if the excretion does not become normal, surgical interference is contra-indicated. Sometimes one finds that a no-threshold substance (*e.g.* creatinine) is being retained. Retention of urea by itself is not important, because along with this retention one may find such conditions as an excessive excretion of phosphates or a retention of chlorides, which are more responsible for the symptoms. The kidney does not function as a whole under abnormal conditions, and if one adheres too rigidly to one criterion of functional efficiency abnormalities may be overlooked.

Dr. J. S. Haldane expressed the view that under normal conditions the kidney regulates the diffusion pressure of water, but that under some abnormal conditions the level set by the kidney is not that required by the tissues.

Prof. P. T. Herring showed some slides of the skate's kidney, which demonstrated the direct excretion of substances into the kidney tubule. He stated that normally the kidney has a constant function, but in disease the function is variable, being influenced by other organs. A study of the comparative structure of the kidney in various animals may help to show how various parts of the kidney tubule function; part may be absorptive and part excretive.

Prof. A. Krogh (Copenhagen) pointed out that the concentration of urea is the same throughout the tissues, but that it may be present in different concentrations in the various secretions.

Prof. T. H. Milroy re-emphasised the uniformity in concentration of urea in blood and muscle. He added that an increase in concentration of urea in the blood is followed by a latent period before the extra urea is eliminated. The concentration in blood and muscle falls slowly to the former level.

Dr. C. L. Evans thought that local circulatory changes in different parts of the kidney might affect the excretion of different substances by different parts of the tubule. The circulatory changes in arteriosclerosis is a case in point.

Dr. E. P. Poulton stated that in the arterio-sclerotic kidney there is a marked difference between the two parts of the kidney and slight urea retention. In azotoic nephritis urea excretion is damaged, but the chlorides are not retained.

Sir James Mackenzie desired that more attention should be paid to the interrelation of kidneys and other excretory organs, such as the skin and bowels.

Prof. E. P. Cathcart opened a discussion on "Heavy Muscular Work." Heavy muscular work requires a co-ordination of the muscular, circulatory, respiratory, and nervous systems. In carrying out heavy work rest periods are important, but the data concerning the number and duration of them are not yet satisfactory. Overwork is prevented by two factors of safety, namely, fatigue, which is slow in onset and may be produced by any degree of work, and collapse, which is sudden in onset, probably due to heart failure, and not to lack of oxygen-supply to muscles. The former is hastened by monotony, such as in marching, and the latter occurs sooner if the work involves a static or maintained element. The effects of training and of diet are important in determining the power to carry on work. All movements are mixed, but some recent experiments may be quoted as indicating a division into three varieties of work, namely, positive, such as lifting a weight; negative, such as

lowering a weight; and static, such as maintaining a weight. The first two correspond to isotonic conditions of contraction, and the last to isometric contraction. As a measurement of the expenditure of energy in these forms of work a subject was given the task of lifting a weight on his hand, lowering the same weight and holding it steady both in the prone and supine positions, the rate of movement being controlled by a metronome:—

Form of work	Calories per sq. m. per hour
Positive	150·9
Negative	124·5
Positive and negative	180·5
Movements without weight	60·1
Static	94·6

In spite of the apparent severity of static work in producing fatigue the metabolism is not excessive, and the fatigue may be due to interference with the circulation.

Prof. A. V. Hill showed curves founded on the heat production of isolated frog's muscles, indicating that maintenance of a contraction is expensive, requiring ten times as much energy expenditure. He also gave results obtained by moving a flywheel at different rates of speed. The rapid rates of movement waste energy because the change of form of muscle requires work to be done in overcoming the viscosity of muscle, whilst slower rate of movement allows a larger proportion of energy to appear as external work. It is important to find out the most efficient relation between the work to be done and the rate at which it should be carried out.

Prof. H. Briggs described the physical endurance tests used during the war. He showed curves relating the variation of energy expended with the work done. A normal load is one which can be continued indefinitely. It was found that well-trained men get assistance from breathing oxygen only when doing excessive work, whilst a man in poor condition is helped by breathing oxygen with smaller loads. Stamina is the ability to maintain work. It appears that habitual hard work may maintain a man's stamina to greater ages than is found in sedentary individuals.

Dr. J. S. Haldane quoted experiments on the circulatory side of work. These experiments were made on man, the lungs being used as an aerotonometer. With increasing severity of work the blood-flow increases exponentially, whilst the percentage of oxygen desaturation of the blood rises logarithmically, and the output per heart-beat remains almost uniform. Therefore, the pulse-rate varies with the blood-flow. In a few individuals in whom the percentage of oxygen utilisation is already high the output of the heart increases as well as the rate of beat. Acapnia decreases circulation-rate, and is thus unfavourable to work.

Prof. A. V. Hill reported some results on pulse conduction in relation to blood-pressure, using the hot-wire sphygmograph. The pulse conduction can be expressed by

$$3\cdot57/\sqrt{\frac{\text{per cent. increase of arterial volume}}{\text{per mm. Hg increase in pressure.}}}$$

By measuring systolic and diastolic pressures and the rate of pulse conduction it is possible to estimate the increase in volume of the arterial reservoir at each heart-beat.

Prof. A. D. Waller described the simplified method for the estimation of physiological cost of work done under various industrial conditions. He suggested that, instead of the various arbitrary terms such as sedentary, light, medium, and heavy work, one should use the energy expenditures of 100, 200, 300, and 400 kilogram metres respectively.

Prof. A. Krogh laid emphasis on the effect of diet on the respiratory quotient and on efficiency. For short experiments a diet containing plenty of carbohydrate is better for maintained exertion. He criticised Prof. Waller's technique, but said that it was probably satisfactory for the investigation of energy expenditure under working conditions in industry. Prof. Waller's methods were criticised by several others. Some criticisms were on technical points, such as the accuracy of dry meters, temperature and pressure measurements or the size of bag used in collecting the expired air, and some were on the results, namely, the low carbon dioxide output in his published work. As Prof. Briggs pointed out, there may be greater sources of error neglected by both sets of workers than those due to the errors of analysis.

The discussion terminated by a paper on "The Economy of Human Effort in Industry" by Mr. E. Farmer. The aim of his study was to find more rapid methods of carrying out industrial processes. One must see the effect on output without the stimulus of special pay. The principles to be used in devising new methods are to encourage smooth movements without marked change in direction and to avoid the intervention of discrimination. He gave examples of increased output in packing chocolates and in metal polishing. Further points requiring study are: What is monotony, what is the influence of noise, and what is the influence of vibration on the workers?

A few individual papers were given.

Prof. A. Krogh described a simple apparatus, consisting of a volume recorder containing soda lime, for measuring oxygen consumption. The soda lime absorbs all carbon dioxide and the volume decrease as recorded on a kymograph gives a measure of the oxygen absorption.

Dr. J. C. Drummond gave an interesting account of some recent work in connection with vitamins and their relation to public health. Green plants and fruits are the main source of vitamins. Dairy products are good in furnishing the vitamins provided that the cows have been fed on green food containing them. The plankton in the sea by the presence of green plants is a source of vitamins which we obtain in fish and fish-oils. It is important that industrial populations should obtain a proper supply of vitamins, because a relative deficiency in them may cause ill-health without the appearance of such diseases as scurvy or beri-beri.

Dr. F. W. Edridge-Green reported experiments on mixing white light with spectral colours. He was followed by Dr. Shaxby, who described a useful instrument consisting of a grating spectroscope with two collimators by which the spectra are formed in reversed order. By a shutter in the eye-piece it is possible to compare monochromatic patches in reversed order.

Dr. R. J. S. McDowall read a paper on "The Independence of the Pulmonary Circulation as shown by the Action of Pituitary Extract." Tracings were shown in which the pulmonary pressure was seen to vary independently of the systemic circulation.

Dr. E. P. Poulton and Dr. W. W. Payne read a paper on "Epigastric Pain." They consider that epigastric pain is not necessarily referred pain, but that it may be due to spasmodic contractions of the œsophagus, stomach, or duodenum.

A number of demonstrations were given, and one

afternoon was spent seeing some of these at the Clinical Laboratory, Royal Infirmary. Amongst these demonstrations were Dr. R. K. S. Lim, demonstration of the mucoid cells of the stomach; Dr. E. P. Poulton and Dr. W. W. Payne, peristalsis of the human œsophagus; Mr. McClure, psychogalvanic reflex; and Prof. J. Meakins, respiration with decreased volume per respiration, with and without oxygen, and effect of resistance to breathing on respiration at rest and whilst working.

The Week in West Africa

AT a meeting of the Royal Anthropological Institute held on December 13 Mr. Northcote W. Thomas read a paper on "The Week in West Africa." He said there were in West Africa a number of sub-divisions of the lunar month, such as 16-day periods, 10-day periods, and the like, the origin of which was either in the market or in some religious belief. There were, in addition, a number of shorter units, comparable to our week, of more uncertain origin; they ranged in length from two to eight days. They were very rarely sub-divisions of the month, and there was reason, where the week is synchronised with the month, to suspect foreign influence. Generally speaking, the month in West Africa was of small importance and played no part in economic or religious life; it was reckoned from the day on which the new moon was first seen, but the native can only very rarely say of how many days it consists. There was no less uncertainty as to the length of the year; few, if any, tribes had any exact knowledge of its length. The calendar was sometimes adjusted by the recognition of two years of different length, as in Benin, where the female year seems to have been about 340 days in length.

The week has been traced to a religious origin. Webster has regarded the "rest day" as its germ, but the rest day is an institution of agricultural people, and there are many such peoples in Africa who have no week. On the other hand, the distribution of the market is practically conterminous with that of the week, and it is probable that the calendar first came into existence as a means of indicating the market day. We have, however, little or no evidence to show why the different units were chosen. A certain number of day-names are derived from names of deities, notably on the Gold Coast, but, generally speaking, the kind of work done on a given day or the market attended is the decisive factor, and consequently they are used only in a small area. To this there is one striking exception; the Ibo day-names, used also in a different order in Benin City, are found everywhere from the Niger to the Cross River, but we are ignorant of their meaning.

The four-day week of the Lower Niger, which appears to be independent of the week of the Congo, seems to occupy the largest area; but we know too little of the distribution of the five- and six-day weeks, especially in French territory, to make any very definite assertion. There is good reason to suppose that a non-Mohammedan seven-day week was known; some of these weeks are clearly expanded from an earlier four-day week, but they have native, not Arabic, names.

Scientific Research and Industrial Development.

IN a lecture on "The Benefits of Research to Corporations" (No. 18, R. and C. Series of Nat. Res. Council, U.S.A., 1921) Dr. Charles L. Reese, chemical director of the de Pont de Nemours Explosives Co., U.S.A., gives examples of the advantages which accrue when a large industrial concern is equipped with a staff capable of applying scientific knowledge to the improvement of materials and processes.

Before the war this important company had already systematised its procedure by developing a system of records and costing, and had completed a number of investigations which had been the means of saving money, resulting, for example, in methods for shortening the time of separation of nitroglycerine from its acids, increasing its yield, preventing its freezing in dynamites, and for nitrating cellulose by the use of the mechanical dipper. Studies from the company's laboratories on the nitration of toluene and of the characteristics of nitrocellulose propellants became of great importance when war broke out, as did also a process for the recovery of a considerable proportion of the alcohol used in gelatinising the propellant, this leading to a direct saving in corn—estimated at ten million bushels—which thus escaped being fermented.

During the war enormous extensions were made by the company for the production of nitrocellulose powder, trinitrotoluene, picric acid, amatol, and tetryl, and in this connection it is stated that the staff of the chemical and mechanical research departments of the firm was increased in number from 212 to 987, with an expenditure on experiment and research of 3,360,000 dollars for four years of the war, the output of military explosives being seven million tons.

Since the war the company has transferred its research organisation with success to the production of dyes, and is spending, and is prepared to spend, many millions of dollars on research to meet German competition, but protection is considered to be essential at present to the existence of the industry.

The address is interesting as giving an idea of the scope and the methods of a large chemical concern in utilising the services of scientific men for the investigation of new processes and the conservation of materials. A custom obtains with the company of recompensing inventors by means of a bonus in the form of the company's stock, in some cases sufficient to make them independent.

Little mention is made, however, of research on the theory of explosives, on which doubtless much work has been done by the staff. A few remarks may be made as to some subject-matter of the claims. Thus, while the mechanical dipper was undoubtedly an advance for obtaining output on the old pot-process of making nitrocellulose, the Thomson displacement process as used in this country and in France also greatly reduces handling of the material and eliminates fuming off, which appears still to occur occasionally with the mechanical dipper. Much is made of the "work found necessary to develop satisfactory methods for loading that very successful high explosive developed in England known as amatol, a mixture of trinitrotoluene and ammonium nitrate," but it is understood that an enormous

number of shell was filled with amatol by the methods supplied from this country. Again, tetryl, trinitrophenylmethylnitroamine, not "tetranitro-dimethylaniline," as stated, was not used exclusively in Germany before the war, but was made here also on the manufacturing scale.

The address, however, is of interest as showing a practical appreciation of the need for the application of scientific method in the development of old, and the acquisition of new, industries.

University and Educational Intelligence.

BIRMINGHAM.—The reports of the Council and of the Principal to be presented to the Court of Governors at the annual meeting on February 9 have been issued. The Principal appeals for more liberal provision of both undergraduate and post-graduate scholarships, and lays stress upon the difficulties which financial stringency imposes on the advancement of research. He reminds the Governors that "the war revealed the obvious, but often forgotten, truth that trained minds cannot be improvised, and that success in international competition will go to the nation which, by laborious and patient organisation, provides, through its universities, disciplined workers."

The extension of the University library is reported with satisfaction as a step in the direction of a more complete provision of that vital need of research workers. The overcrowding of the Mason College buildings is regarded as a grave menace to the continued expansion of the departments of medicine, biology, arts, and education. The obvious remedy is to transfer the biological departments to new buildings at Edgbaston, but as this would involve great expenditure of money the alternative of restricting entries to all the departments at present housed in Mason College may have to be faced in the near future.

The Principal appeals especially for more support from the districts surrounding the city, which send a large proportion of the students at present in the University, reminding them that "we cannot have it both ways: unrestricted admission of all the fully qualified and the withholding of a substantial contribution towards the financial cost of a university education."

Reference is made to the problem of adult education and the way in which the University is trying to do its share of this important work. "All who keep closely in touch with the main currents of educational opinion are impressed with the increasing insistence of the demand as well as with the complexity of the task involved in an 'educated democracy.' It would be disastrous if the handling of the problem became political; the provincial universities by sympathy and wise statesmanship, perhaps more than any other organisations, can avert this danger."

The Court of Governors is to be asked to confer the title of emeritus professor on Prof. J. H. Muirhead.

The assistance of the Birmingham Chamber of Commerce in completing the fund for a chair of Italian (which was started by Mr. Arthur Serena's gift of 5000*l*.) is gratefully acknowledged by the Council.

The appointment of Mr. Maurice Nicoll to the lectureship in psychotherapy, endowed by Sir Charles Hyde, is reported.

In commemoration of the work of Prof. P. F. Frankland, a fund has been subscribed for providing a Frankland medal and a prize of books to be given annually to the best student in practical chemistry.

A bequest of 2000*l*. under the will of the late Richard Peyton becomes available, by the death of his widow, "for the advancement of music."

Calendar of Industrial Pioneers.

January 26, 1891. Nicolas August Otto died.—Originally a commercial traveller, Otto began work on the gas engine in 1854. In 1867 with Langen he brought out the Langen and Otto atmospheric engine, and in 1876 he introduced the engine working on the Otto cycle, which proved to be the turning point in the history of gas motors.

January 27, 1848. Josiah Christopher Gamble died.—A pioneer among alkali manufacturers, Gamble was born in Ireland in 1776. He graduated at Glasgow University and became a Presbyterian minister. After a few years he abandoned the Church, started small works at Dublin for the manufacture of sulphuric acid, bleaching powder, and alum, and in 1828 with Muspratt founded the first chemical works at St. Helens.

January 27, 1885. Edward Davy died.—A contemporary of Wheatstone and Cooke, Davy invented an electric telegraph, experimented with a mile of wire in Regent's Park, and in 1837 at Exeter Hall exhibited his needle telegraph. In 1839 he sailed for Australia, where he became medical officer of health and Mayor of Malmesbury.

January 28, 1829. Thomas Tredgold died.—Known for his valuable writings on carpentry, the strength of materials, and the steam engine. Tredgold began life in the North of England as a journeyman carpenter. He studied mathematics, chemistry, and architecture, contributed to the "Encyclopædia Britannica" and the *Philosophical Magazine*, and made original investigations. He died in London at the age of forty, worn out by his labours.

January 28, 1864. Benoit Paule Emile Clapeyron died.—From the Ecole Polytechnique Clapeyron entered the mining service, taught in the School of Public Works at St. Petersburg, and on his return to France took part in the construction of some of the earliest French railways. He wrote on the mechanical theory of heat, and it was through his work that Kelvin was led to the study of Carnot's famous memoir. Clapeyron in 1858 succeeded Cauchy as a member of the Paris Academy of Sciences.

January 29, 1882. Alexander Lyman Holley died.—A graduate of the Brown University, Providence, Holley engaged in practical engineering, and in 1860 published an important work on American and European railway practice. He afterwards became a great ironmaster. The inscription on his monument in Washington Square, New York, states that he was "foremost among those whose genius and energy established in America and improved throughout the world the manufacture of Bessemer steel."

February 1, 1885. Stanislas Charles Henri Laurent Dupuy de Lôme died.—In 1848–52 Dupuy de Lôme built the *Napoléon*, the first steam line of battleship. About five years later he converted the finest two-decker in the French Navy, also called the *Napoléon*, into the *Gloire*, the first fully armoured sea-going ship ever seen. She was 256 ft. long, of 900 h.p., carried thirty-six guns, and was protected by 5 in. of iron and 26 in. of timber. Dupuy de Lôme was for some years Chief Constructor of the French Navy.

February 1, 1885. Sidney Gilchrist Thomas died.—A clerk in a London police court, Thomas studied chemistry and in 1870 attacked the problem of the dephosphorisation of pig-iron in the Bessemer converter. By 1875 he had solved the problem, and with the assistance of his cousin, Percy Gilchrist, and others, the commercial triumph of his important discovery was assured. His grave is in the Passy Cemetery in Paris.

Societies and Academies.

LONDON.

Royal Society, January 19.—Sir Charles Sherrington, president, in the chair.—L. **Hill**, H. M. **Vernon**, and D. H. **Ash**: The kata-thermometer—a measure of ventilation. The kata-thermometer is used in ventilation inquiries to estimate (1) the cooling, (2) the evaporative power of the air on a surface at body-temperature, and (3) as an anemometer to indicate the velocity of air-currents. Certain discrepancies having arisen, the "kata" formulæ have been re-investigated, using the large wind-channels at the National Physical Laboratory, and for low velocities the method of moving the "kata" through the air in a whirling arm, taking count of the effect of "swirl."—Lt.-Col. C. B. **Heald** and Major W. S. **Tucker**: Recoil curves as shown by the hot-wire microphone. The hot-wire microphone has been employed to measure body recoil as the result of heart action, and the records measure quantities proportional to the kinetic energy imparted to the body by motions of the blood. Thus slow-moving displacements, such as those of breathing, are not recorded. The apparatus can be standardised, giving the same responses from day to day for the same body recoils, and the kinetic energy of the body can be expressed in C.G.S. units. The results are consistent with physiological data.—E. W. A. **Walker**: Studies in bacterial variability: The occurrence and development of dys-, eu-, and hyper-agglutinable forms of certain bacteria. In the enteric and dysenteric groups of bacteria dys- and hyper-agglutinable forms occur. Both may be obtained from one eu-agglutinable strain of a bacillus. In agglutination tests a highly dys-agglutinable bacillus may fail to agglutinate with a serum that agglutinates the culture from which it was derived up to 1 in 1000. It may also fail to absorb from the serum the agglutinins specific to that culture. Noteworthy differences in behaviour thus exist between different individuals of a single culture. These facts may help to throw light on the problem of seriological strains.—Marjory **Stephenson** and Margaret **Whetham**: Studies in the fat metabolism of the timothy grass bacillus. During the growth of the timothy grass bacillus on a medium of inorganic salts, including ammonia as the sole source of nitrogen, glucose, and sodium acetate, the formation of protein, nitrogen, and fat was followed and correlated with the disappearance of glucose and acetate. No intermediate decomposition products of glucose were found. The growth of the organism on possible intermediate products of the breakdown of glucose was then studied. The growth on lactic acid was very similar to that on glucose alone. Growth on acetic acid was negligible. Growth on acetic and lactic acid showed that lactic acid enabled the organism to utilise the acetic acid. The acetic acid utilised in the presence of lactic acid or glucose served to increase the proportion of lipoid material formed, and not to increase the general growth of the organism. Growth on propionic and butyric acids was like that on lactic acid.—J. A. **Gardner** and F. W. **Fox**: The origin and destiny of cholesterol in the animal organism. Pt. 12: The excretion of sterols in man. Measurements of the intake and output of sterols in twenty-six cases on known diet show that in every case, except one, there was an excess of output over intake. The average daily negative balance was 0·3 gram, but individual balances were very variable. A considerable portion of the cholesterol of the food and of the bile is re-absorbed in the intestine along with the bile salts, but this process appears to be limited by the reduction of cholesterol to bi-hydrocholesterol in the intestine, a process especially characteristic of the adult human subject. The excess of output of cholesterol over intake leads to the conclusion that there is some organ in the body capable of synthesising cholesterol. The intake of unsaponifiable matter not precipitable by digitonin is much larger than the output.—S. J. **Lewis**: The ultra-violet absorption spectra and the optical rotation of the proteins of the blood sera. The absorption curve of pseudo-globulin is constant and the same for both the horse and human varieties. The curve for eu-globulin differs considerably from that for pseudo-globulin in extinction coefficients, but not in general form. The absorption curves for the horse and human varieties of albumin are similar, except for a constant ratio in their magnitudes, and this difference may be due to the association of an aggregate possessing little or no selective absorptive power, *e.g.* an aliphatic amino-acid or a polypeptide, with the principal aggregate. The close similarity in form of all the curves when corrected to a common amplitude, and the fact that the amplitudes are nearly all simple multiples of a common factor, point to similarity of constitution amongst these proteins and to a variable "concentration" of the active group. Processes for the separation and purification of the proteins have been elaborated.

Mineralogical Society, January 10.—Mr. A. Hutchinson, president, in the chair.—C. E. **Tilley**: Density, refractivity, and composition relations of some natural glasses. The glasses investigated fall into two groups, (*a*) tektite glasses and (*b*) volcanic glasses. The characteristics of the former confirm their divergence from volcanic glasses, and support the theory of their meteoritic origin. The specific refractivities of five analysed glasses are compared with the values calculated from the specific refractivities of their component oxides, and a notable correspondence is revealed. The influence of contained water on the specific refractivity is discussed and some figures bearing on the volume-change accompanying the passage from the vitreous to the crystalline state are given.—H. H. **Thomas** and E. G. **Radley**: The so-called "avanturine" from India, with an analysis of the contained mica. The stone is a quartz-schist, and owes its colour to plates of green fuchsite arranged parallel to the planes of foliation. The mica contains 1·77 per cent. Cr_2O_3 and a little vanadium; its optical characters are described. The probable source of the stone is discussed and the deterioration of the stone by heat and other causes is explained.—A. **Russell** and A. **Hutchinson**: Laurionite and paralaurionite from Cornwall. Laurionite associated with phosgenite and anglesite in a cavity in limonite is described in a specimen obtained from the collection of John Hawkins, of Trewithin, Cornwall. The locality is probably Wheal Rose, Sithney. Paralaurionite occurs with phosgenite in a very similar specimen in the collection of the late H. J. Brooke, said to come from Wheal Confidence, Newquay.—A. **Russell**: A discovery of pitchblende at Kingswood Mine, Buckfastleigh, North Devon. Pitchblende, occurring in a north and south lode associated with chloanthite, and native bismuth is described. The discovery shows promise of being of some economic importance.—W. A. **Richardson**: The distribution of oxides in Washington's collected analyses of igneous rocks. Frequency curves are given for all the oxides, and show considerable differences from those previously published. The silica curve is the most interesting, and shows two maxima, one at 52 per cent. and the other at 72 per cent. SiO_2. The frequency curve for SiO_2 can be matched by a combination of two normal curves or error with origins

on the 52 and 72 per cent. lines.—W. A. **Richardson**: A simplification of the Rosiwal method of micro-analysis. A method by which, using a drawing apparatus, the lengths of component minerals of a rock can be projected on to separate strips of paper and directly summed is described.—Dr. A. **Schoep**: The absence of cobalt in cornetite from Katanga, Belgian Congo. Microchemical tests made on carefully selected crystals from the original locality (Star of the Congo Mine) prove that cobalt is present only in associated black spots of heterogenite. The mineral is thus a hydrated phosphate of copper, agreeing completely with that recently described from Northern Rhodesia.

PARIS.

Academy of Sciences, January 9.—M. Emile Bertin in the chair.—C. **Lallemand**: The genesis and present state of the science of the abacus.—T. **Varopoulos**: A class of increasing functions.—P. **Humbert**: The product of Laplace relative to certain hypercylinders.—G. **Dumas**: A normal table relating to unilateral surfaces.—A. **Denjoy**: Functions defined by series of rational fractions.—B. **Gambier**: Surfaces and varieties of translation of Sophus Lie.—C. **Nordmann** and M. **Le Morvan**: Observation of an abnormal star by the heterochrome photometer of the Paris Observatory. The star 13 Cepheus presents some singular anomalies. It belongs to the spectral type A (hydrogen stars), but has a yellow coloration. The colour photometer shows that the light intensity is distributed in the spectrum in such a manner that the more refrangible rays are proportionally less intense than in any of the stars hitherto studied, not only of this type, but also of types F and G. It is possible that the atmosphere surrounding this star possesses exceptional absorbing power.—E. **de Martonne**: The massif of Poïana Ruska and the correlation of the erosion cycles of the southern Carpathians.—E. **Carvallo**: The principle of relativity in dielectrics.—P. **Chevenard**: The expansion of chromium and the chrome-nickel alloys over a wide temperature interval. A differential dilatometer was employed in which the standard bar was a nichrome (with 10 per cent. of chromium), the law of expansion of which had been carefully determined by direct methods. A diagram is given of the results on commercially pure chromium (98·3 per cent.) and five chrome-nickel alloys. The diagram gives the coefficients of expansions as functions of the temperature over the range 0° C. to 900° C.—M. **Faillebin**: A mixed organo-metallic compound of aluminium. Aluminium and methylene iodide in dry ether in the presence of a little iodine react in two ways, the principal reaction giving $CH_2{\cdot}AlI$ and AlI_3, the subsidiary reaction AlI_3 and ethylene.—J. **Barlot** and Mlle. M. T. **Brenet**: The determination of fatty acids by the formation of complex compounds with uranyl and sodium. Streng's reagent (acid solution of uranyl nitrate) is known to give a precipitate of a double salt with sodium acetate. Similar precipitates are obtained with the sodium salts of higher fatty acids, but only if the acid contains an even number of consecutive carbon atoms. Thus formates, propionates, *iso*butyrate, and normal valerates give no precipitate, but the reaction is obtained with acetic, normal butyric, fermentative valeric and normal caproic acids.—Y. **Milon** and L. **Dangeard**: A Redonian formation (Upper Miocene) forming ravines with the Eocene clays to the south of Rennes (Ille-et-Vilaine) containing iron minerals.—E. **Zaepffel**: The mechanism of the orientation of leaves. The movements of the leaf are connected with the distribution of water, and this distribution is influenced by the mobile starch.—C. **Douin**: The gametophyte of the Marchantiæ.—L. **Plantefol**: The toxicity of various nitrophenols for *Sterigmatocystis nigra*. Experiments were carried out with three isomeric nitrophenols, dinitrophenol, and trinitrophenol. All these proved more toxic to the mould than phenol itself. The three mononitrophenols differed in toxicity, the para-compounds being the most toxic. The dinitrophenol had the greatest effect in inhibiting the growth of the mould of any of the substances tried; it is nearly 300 times more toxic than phenol.—E. **Chatton**: Polymorphism and maturation of the spores of Syndinium.—R. **Sazerac** and C. **Levaditi**: The use of bismuth in the prophylaxy of syphilis. Sodium potassium tartarobismuthate, administered in intramuscular injection, acts preventively against syphilitic infection, and the same salt applied locally in the form of salve acts preventively even after infection. The conclusions were arrived at after experiments on rabbits.

Diary of Societies.

THURSDAY, JANUARY 26.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—S. Gordon: Sea Birds and Seals.

ROYAL SOCIETY, at 4.30.—W. B. Hardy and Ida Doubleday: Boundary Lubrication: The Paraffin Series.—Prof. W. A. Bone, A. R. Pearson, E. Sinkinson, and W. E. Stockings: Researches on the Chemistry of Coal. Part 2: The Resinic Constituents and Coking Propensities of Coals.—Dr. J. A. Crowther and B. J. Schonland: The Scattering of β-rays.—Ann C. Davies: The Minimum Electron Energies associated with the Excitation of the Spectra of Helium.—C. N. Hinshelwood, H. Hartley, and B. Topley: The Influence of Temperature on Two Alternative Modes of Decomposition of Formic Acid.—Prof. C. V. Raman: The Molecular Scattering of Light in Water and the Colour of the Sea.

ROYAL AERONAUTICAL SOCIETY (Students' Meeting) (at Royal Society of Arts), at 7.—C. Daniel: Practical Points in Fuselage Construction.

INSTITUTION OF LOCOMOTIVE ENGINEERS (London) (at Caxton Hall), at 7.15.—C. J. Allen: The Influence of Design on Express Locomotive Performance.

CONCRETE INSTITUTE, at 7.30.—E. B. Moullin: Capillary Canals in Concrete, and the Percolation of Water through Them.

ROYAL MICROSCOPICAL SOCIETY (Metallurgical Section), at 7.30.—H. Wrighton: Demonstration of Polishing Metal Specimens.

ROYAL SOCIETY OF MEDICINE (Urology Section), at 8.30.

SOCIETY OF ANTIQUARIES, at 8.30.

FRIDAY, JANUARY 27.

ASSOCIATION OF ECONOMIC BIOLOGISTS (in Botanical Lecture Theatre, Imperial College of Science and Technology), at 2.30.—Prof. E. P. Stebbing and others: Discussion: The Importance of Scientific Research in Forestry and its Position in the Empire.

ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.—A. L. Howard: The Timbers of India and Burma.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.—T. H. Littlewood: The Diffusion of Solutions.—H. R. Nettleton: A Special Apparatus for the Measurement at Various Temperatures of the Thomson Effect in Metals.—J. J. Manley: A Defect in the Sprengel Pump: its Cause and the Remedy.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Hunterian Lecture: The Facial Characteristics of the Races native to India.

ROYAL SOCIETY OF MEDICINE (Study of Disease in Children Section), at 5.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—L. M. Jockel: Fuels and the Boiler-house.

ROYAL SOCIETY OF MEDICINE (Epidemiology and State Medicine Section), at 8.—Dr. S. M. Copeman, Dr. R. A. O'Brien, Dr. A. J. Eagleton, and A. T. Glenny: Experiences with the Schick Test, and Active Immunisation against Diphtheria.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Viscount Burnham: Journalism

SATURDAY, JANUARY 28.

ESSEX FIELD CLUB (in Physical Lecture Theatre, West Ham Municipal College), at 3.—C. Nicholson: The Rosy-Marbled Moth (*Erastria venustula*) in Britain (with special reference to Essex).—G. Morris: Some Neolithic Sites in the Valley of the Essex Cam.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. C. Macpherson: The Evolution of Organ Music (2).

MONDAY, JANUARY 30.

INSTITUTE OF ACTUARIES, at 5.—G. King: A Short Method of Constructing Select Mortality Tables: Further Developments.

ROYAL SOCIETY OF ARTS, at 8.—C. Ainsworth Mitchell: Inks (Cantor Lectures) (2).

MEDICAL SOCIETY OF LONDON, at 9.—Sir Leonard Rogers: Amœbic Liver Abscess: Its Pathology, Prevention, and Cure (Lettsomian Lectures) (1).

TUESDAY, JANUARY 31.

ROYAL HORTICULTURAL SOCIETY, at 1.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. H. H. Turner: Variable Stars (1); Short Period Variables.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—H. H. Wrench: Our Old Village Churches and their Story.
ILLUMINATING ENGINEERING SOCIETY (Joint meeting with the Royal Aeronautical Society) (at Royal Society of Arts), at 8.—Lt.-Col. L. F. Blandy and others: Discussion: The Use of Light as an Aid to Aerial Navigation.

WEDNESDAY, FEBRUARY 1.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—C. E. N. Bromehead: Some Notes on the New 6-inch Geological Survey of London and the Influence of the Geology on the History of the Area.
ROYAL SOCIETY OF MEDICINE (Surgery Section), at 5.30.—Major H. D. Gillies: Demonstration of Plastic Surgery.
INSTITUTION OF ELECTRICAL ENGINEERS (Wireless Section), at 6.—Major J. Erskine-Murray: (*a*) The Determination of the Decrement of a Distant Sending Station; (*b*) Some New Methods of Radio-Navigation.
ENTOMOLOGICAL SOCIETY OF LONDON, at 8.
ROYAL SOCIETY OF ARTS, at 8.—A. Wilcock: Surface Printing by Rollers in the Cotton Industries: A Comparison with other Processes of Printing Patterns for Cretonnes, Dress Materials, Wallpapers, etc.
SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at Chemical Society), at 8.—J. L. Lizius and N. Evers: Studies in the Titration of Acids and Bases.—Dr. J. C. Drummond and A. F. Watson: The Sulphuric Acid Reaction for Liver Oils and its Significance.—W. Dickson and W. C. Easterbrook: The Quantitative Separation of Nitrobody Mixtures from Nitro-glycerine.

THURSDAY, FEBRUARY 2.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Napier Shaw: Droughts and Floods (1).
ROYAL SOCIETY, at 4.30.—*Probable Papers*.—C. Shearer: The Oxidation Processes of the Echinoderm Egg during Fertilisation.—J. Schmidt: The Breeding Places of the Eel.—J. Gray: The Mechanism of Ciliary Movement.—J. Gray: The Mechanism of Ciliary Movement. II. The Effect of Ions on the Cell Membrane.—J. S. Huxley and L. T. Hogben: Experiments on Amphibian Metamorphosis and Pigment Responses in Relation to Internal Secretions.
LINNEAN SOCIETY OF LONDON, at 5.—F. Johanssen: The Canadian Arctic Expedition.—Dr. J. C. Willis and U. Yule: Some Statistics of Evolution and Distribution in Plants and Animals, and their Significance.—Mrs. E. M. Reid: Note on Fossil Floras.
ROYAL SOCIETY OF MEDICINE (Medicine Section), at 5.—Discussion on the Treatment of Gastric Ulcer. Speakers: Sir William Hale-White, Sir William Willcox, Sir Berkeley Moynihan, and Mr. Sherren.
INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—L. J. Romero and J. B. Palmer: The Interconnection of A.C. Power Stations.
CHEMICAL SOCIETY, at 8.—E. J. Hartung: The Action of Light on Silver Bromide.—C. K. Ingold: The Structure of the Benzine Nucleus. Part I. Intra-nuclear Tautomerism.—C. K. Ingold: The Structure of the Benzine Nucleus. Part II. Synthetic Formation of the Bridged Modification of the Nucleus.—C. K. Ingold and H. A. Piggott: The Structure of the Benzine Nucleus. Part III. The Suppression of Intra-nuclear Change.

FRIDAY, FEBRUARY 3.

ROYAL SOCIETY OF MEDICINE (Laryngology Section), at 4.45.
ROYAL ASTRONOMICAL SOCIETY, at 5.—Geophysical Discussion on the Depth of Origin of Earthquakes. Prof. Love in chair. Speakers: Prof. Turner, Prof. Lamb, R. D. Oldham, Dr. H. Jeffreys, Prof. Knott, Dr. C. Davison, and Major Taylor.
ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. K. M. Walker: The Nature and Cause of Old Age Enlargement of the Prostate (Hunterian Lecture).
EUGENICS EDUCATION SOCIETY (at Royal Society), at 8.—Prof. H. J. Fleure: Some Social Bearings of Race Study.
JUNIOR INSTITUTION OF ENGINEERS, at 8.—Major W. Gregson: Utilisation of Waste Heat from Internal Combustion Engines.
ROYAL SOCIETY OF MEDICINE (Anæsthetics Section), at 8.30.—Discussion on the Uses and Limitations of N_2O and O_2 Anæsthesia. Speakers: Dr. A. L. Flemming and others.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir Francis Younghusband: The Mount Everest Expedition.

PUBLIC LECTURES.

(*A number in brackets indicates the number of a lecture in a series.*)

THURSDAY, JANUARY 26.

UNIVERSITY COLLEGE, at 5.15.—B. S. Rowntree: Industrial Unrest.
KING'S COLLEGE, at 5.30.—Dr. O. Faber: Reinforced Concrete (2).
GRESHAM COLLEGE, at 6.—A. R. Hinks: Astronomy in Daily Use (3).
ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, at 6.—Dr. W. K. Sibley: Alopecia and its Treatment (Chesterfield Lecture).

FRIDAY, JANUARY 27.

METEOROLOGICAL OFFICE (South Kensington), at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (2).
KING'S COLLEGE, at 5.30.—Dr. H. W. Williams: The Peoples of the Caucasus (2); at 6.—Prof. G. Young: Brazil.
TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES (at the Mary Ward Settlement, Tavistock Place), at 5.30.—Dr. H. Crichton Miller: The New Psychology and its Bearing on Education (1).
GRESHAM COLLEGE, at 6.—A. R. Hinks: Astronomy in Daily Use (4).

SATURDAY, JANUARY 28.

LONDON DAY TRAINING COLLEGE, at 11 a.m.—Prof. J. Adams: The School Class (2).
HORNIMAN MUSEUM (Forest Hill), at 3.30.—F. Balfour-Browne: The Life and Habits of Mason Bees.

MONDAY, JANUARY 30.

UNIVERSITY COLLEGE, at 5.—A. T. Walmisley: The Bridges over the River Thames at London.
KING'S COLLEGE, at 5.30.—Dr. J. Steppat: Recent Developments in German Education and Student Life.—Prof. L. L. Fortescue: Wireless Transmitting Valves (2).

WEDNESDAY, FEBRUARY 1.

HORNIMAN MUSEUM (Forest Hill), at 6.—W. W. Skeat: The Living Past in Britain (2).

THURSDAY, FEBRUARY 2.

KING'S COLLEGE, at 5.30.—Dr. O. Faber: Reinforced Concrete (3).
ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN (Leicester Square, W.C.2), at 6.—Dr. J. L. Bunch: Drug Eruptions (Chesterfield Lecture).
CIVIC EDUCATION LEAGUE (at Leplay House, 65 Belgrave Road, S.W.1), at 8.15.—Miss Barbara Low: Psycho-analysis in relation to Civics.

FRIDAY, FEBRUARY 3.

METEOROLOGICAL OFFICE (South Kensington), at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (3).
UNIVERSITY COLLEGE, at 5.—Prof. G. Elliot Smith: The Evolution of Man (1).
KING'S COLLEGE, at 5.30.—Rev. Dr. F. A. P. Aveling: Matter, Mind, and Man.—Dr. H. W. Williams: The Peoples of the Caucasus (3).
TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES (at the Mary Ward Settlement, Tavistock Place, W.C.1), at 5.30.—Dr. H. Crichton Miller: The New Psychology and its Bearing on Education (2).

SATURDAY, FEBRUARY 4.

SALTERS' HALL (St. Swithin's Lane, E.C.4), at 10.30 a.m.—Dr. M. O. Forster: The Relation between Pure and Applied Chemistry.
LONDON DAY TRAINING COLLEGE, at 11 a.m.—Prof. J. Adams: The School Class (3).
HORNIMAN MUSEUM (Forest Hill), at 3.30.—E. Lovett: The Folk-lore of Natural History.

The Influenza Problem.

THE widespread recrudescence of influenza in this country, although on a less fatal scale and of a less virulent type than in the experience of 1918–19, is an unpleasant reminder of our present helplessness in respect of this disease. Many volumes have been written about it. The old Local Government Board issued two reports by Dr. Franklin Parsons, which summarised all we then knew of the epidemic of 1890, and did much to expand our knowledge; and we have now before us an even more portly tome of nearly 600 pages upon the subject, issued by the new Ministry of Health. This report contains valuable historic material, an admirable clinical study of the disease, and suggestive speculations on the statistical aspects of the problem presented by it. These forcibly impress us with the imperfections of statistics dealing with altogether imperfect material. But we cannot be said to have greater knowledge of the disease, from the point of view of preventive medicine, than when Dr. Parsons's reports were issued. This is no reflection on the Ministry of Health; for in every civilised country investigators have similarly drawn a blank so far as guidance for the prevention of the disease is concerned.

We know certain elementary facts which, if they could be universally applied in practice, would prevent influenza from spreading; for the disease is infectious, and it is practicable to lessen the public opportunities of infection by avoiding unnecessary assemblies of people. But how can we avoid infection in social and business life, in view of the early infectivity of the disease, the failure to recognise mild attacks, and the short incubation period, which multiplies centres of infection at a very rapid rate? We commonly fail to prevent the spread of ordinary catarrhs; and this is an index of our incapacity or inertia in relation to the more serious disease.

The mere enumeration of matters concerned with influenza on which we are still ignorant is an almost tedious task. Let us attempt it partially. We know that at uncertain intervals influenza marches, or rather flies, through the world, without any known reason. The epidemics in this country of 1803, 1833, 1837–8, and of 1889–92, are well known, but many occurred in previous centuries, and some have even asserted that the sweating sickness was a type of influenza. We know that when influenza becomes epidemic it tends to recur in secondary and tertiary waves, as in our recent experience. The present outbreak is the fourth since 1918. Dr. Brownlee has given interesting evidence pointing to an appearance of law in the intervals after which recurrences occur; and we may hope to hear more from him on this point, not only as regards this country but also for other countries, as to whether this law holds good internationally.

Knowledge of the natural history of these outbreaks may be expected eventually to give some clue to prevention, though this is not yet visible. But it is not known why influenza takes on a worldwide march at irregular intervals. We may assume that endemic influenzal infection of low virulence and infectivity, for some unknown reason, changes its biological characters, and that one or both of these characteristics may become enhanced; but why? Attempts to associate pandemics with special meteorological conditions have had little or no success; and we are little further advanced than when Sydenham appealed to the "epidemic constitution" of certain years.

As an alternative to the acquirement of enhanced biological properties by the contagion of influenza may be cited the evidence of importation of infection and the rapid spread of the disease from country to country; but this merely puts the practical difficulty further back. Why this exceptional spread from country to country, and why does not influenza prevail, like measles, every second year in a given urban community?

Further light would be more easily obtainable if we were certain that the Pfeiffer bacillus is the true causal agent of influenza; it is not dispossessed from this position, but the evidence of bacteriologists in recent outbreaks has not strengthened its position; and although bacteriologists have isolated the

bacillus from secretions of influenzal patients and grown it in separate culture, they have failed in the crucial test of inoculation in animals to reproduce influenza.

This brings us to our next difficulty. In the absence of a certain bacteriological test, a further obstacle is that there is no characteristic symptom in influenza, like the rash in scarlet fever, or the throat membrane in diphtheria. On the contrary, what is supposed to be influenza assumes several types. At present cases with gastric symptoms are common, with few or no respiratory complications in a proportion of cases. But are we certain that these two types are the same disease? There is much evidence that commonly there is mixed infection; and in the great epidemic of 1918–19, which destroyed more of mankind than the great war, much of the mortality was due to secondary (or primary) invasion of hæmolytic streptococci.

On such an apparently simple point as the immunity conferred by a single attack the evidence is discrepant. Although it did appear that many of those attacked in the summer epidemic of 1918 escaped attack in the terrible epidemic of the following winter, the evidence is not satisfactory. It appears clear that if immunity is conferred by an attack, the immunity is of short duration; and this brings out the further point that inoculation of a vaccine prepared from the Pfeiffer bacillus and the associated coccal organisms cannot be expected to do much good, except perhaps in diminishing the seriousness of pulmonary complications.

Nor have we any plausible explanation of the remarkable change in the age incidence of deaths from influenza. In the epidemic of 1889–92 some 60 to 70 per cent. of all the recorded deaths from influenza occurred among patients more than 55 years old; in the recent epidemic, fatal cases at these ages formed only some 12 per cent. of the total, while about 70 per cent. of the total deaths were of patients less than 35 years old. Does this imply that we have recently been concerned with a different infection, or what is the explanation?

It is noteworthy that coincidently with epidemic influenza, certain other diseases, like cerebro-spinal meningitis and encephalitis lethargica, have prevailed to an exceptional extent. This has been explained by Dr. Hamer and others as implying that we are, in fact, in the grip of a single infection assuming multiform manifestations. But the association was not evident in the 1889–92 epidemic; and it is equally open to us to assume—and there are good grounds for maintaining—that all these diseases, each specific in character, are favoured by the same "epidemic constitution"—or what is concealed under this designation—and that they are not identical diseases.

The preceding incomplete review of the chief of the unknown factors in influenza must necessarily be somewhat depressing. It is well, therefore, to look for a moment at other diseases which, like influenza, at irregular intervals and for unknown reasons, assume world-wide movements, invading mankind in many countries. Among these cholera, plague, and smallpox may be specially mentioned. Yet each of these is entirely controllable, and, so far as a large part of the world is concerned, has been controlled. Cholera is now kept within bounds and almost non-existent in every country with elementary sanitation. Plague is controllable to the extent to which infection by rats and their fleas is stopped: a practicable programme. In smallpox there is the important additional protection of vaccination, and against a population protected by this measure waves of smallpox infection break for ever impotently. The last-named illustration is significant from the point of view of influenza. Both infections are usually received by the respiratory tract. Against one vaccination affords protection, against the other results of inoculation have been more than dubious. The world is waiting for further light. How is influenza and how are respiratory infections in general to be prevented? This is the unconquered region of preventive medicine. It will doubtless be occupied eventually, but after how much delay and on what plan it would be rash to hazard a prophecy.

An Elusive Group of Marine Organisms.

The Free-living Unarmored Dinoflagellata. By C. A. Kofoid and Olive Swezy. (Memoirs of the University of California, Vol. 5.) Pp. viii + 562 + 12 plates. (Berkeley, California: University of California Press, 1921.)

THE University of California at Berkeley, Cal., supported no doubt by large revenues from the State, sets a noble example in publishing valuable contributions to knowledge. In addition to about thirty octavo series in zoology, physiology, and other sciences, the University Press issues large quarto Memoirs, of which the fifth volume is Kofoid and Swezy's "Dinoflagellata," a very notable work of 570 pages and twelve coloured plates. It is the result of observations made by Prof. Kofoid and his pupils over a series of years from 1901 onwards at the marine laboratories of the University of California and the more recently established Scripps Institution for Bio-

logical Research at La Jolla—both by work at sea off the coast of Southern California and by investigation of the beach sands.

The Dinoflagellata form an exceedingly important source of the food supply of the sea both in numbers and in the total mass produced. As synthetic producers of carbohydrates, proteids, and fats they hold high rank amongst microscopic marine organisms, and in abundance they are second only to the diatoms in the plankton, while locally and on occasions they may far outnumber them. These local massive developments are the all but universal cause of the discoloured seas and of the phenomena of luminescence. The present monograph deals with the least-known and most elusive members of the group, the naked or unarmoured forms.

One great difficulty in their investigation is the extreme delicacy of these organisms and their tendency to undergo cytolysis in even a few moments' exposure to light under the microscope. They are unfortunately most sensitive to the action of fixing re-agents, and almost instantaneous distortion and disruption prevent the preservation of permanent preparations. The investigator is therefore limited to rapid and immediate observation of the freshly captured living and usually very active organisms. It is only on a coast such as that of Southern California, where pure oceanic water with a rich pelagic fauna is brought within a few miles of a laboratory equipped like the Scripps Institution, that work such as that of Prof. Kofoid could be carried on. A specially devised net of the finest silk is towed for a very short time at a depth of 80 metres, the catch transferred to a relatively large volume of water, rushed ashore in a fast motor-boat (30 miles an hour), and divided up at once for the microscopes of half-a-dozen assistant observers, a surprising number of new and remarkable forms in exceptionally fine condition being revealed. Ordinary methods of plankton collection and preservation yield no traces of these extremely delicate organisms. This is an excellent example of new and refined methods at sea, such as can be adopted only in connection with a biological station, which are giving new results of great scientific interest. It must not be supposed, however, that all these Dinoflagellates are confined to oceanic water. Some are neritic, and species of Amphidinium, for example, have been found in vast numbers on damp beach sand at several localities in England, California, and elsewhere.

Many of these new unarmoured Dinoflagellates are brilliantly coloured, as the beautiful plates abundantly show, and some are wonderfully organised and specialised for such minute protozoa. Some possess, amongst other "organelles," a complicated ocellus or "eye," with lens, pigment mass, and sensory core, as well as a large mobile tentacle, and groups of nematocysts resembling those of Cœlenterata. The whole group and its subdivisions and the numerous genera, sub-genera, and species are discussed most fully from every point of view—general morphology and relations, minute structure, physiology, history, and distribution. In their nutrition the majority of marine unarmoured Dinoflagellates are holozoic, and even some of those that contain chromatophores and were hitherto supposed to be holophytic are now found to contain ingested foreign bodies in the cytoplasm. What is known of the life-cycles, including encystment, spore formation, binary and multiple fission, and possibly conjugation—and the effects of parasitism in some forms—are all discussed, but it is evident that much has still to be discovered in regard to these matters.

In regard to the evolution of the group, our authors show that it probably arose from the Cryptomonads, and the Dinoflagellata of to-day represent the terminal twigs of a phylogenetic branching. The attempt to find ciliate affinities through the remarkable genus Polykrikos is rejected as a misinterpretation. A new form, Protodinifer, is regarded as bridging the gap between the two main groups of Dinoflagellates, the Diniferidea and the Adiniferidea, but it may be pointed out that "Protodinifer" is clearly identical with the *Pelagorhynchus marinus* of Pavillard (*Comptes rendus*, January, 1917). Amongst notable changes in the more familiar classifications of the text-books are the removal of Noctiluca from the Cystoflagellata and its inclusion in the Gymnodinoidæ, and the abolition of the Pyrocystaceæ of Murray, Apstein, West, and others, as these latter organisms are now to be regarded as merely phases in the life-history of other Dinoflagellates.

In addition to the nematocysts in Nematodinium and Polykrikos and the ocellus in Pouchetia, etc., the most remarkable further specialisation is seen in the highly developed appendage or "prod," with protractile and retractile fibrillæ, which reaches its climax in the genus Erythropsis. The authors, in pointing out the cœlenterate resemblances of the nematocysts and the tentacle placed on the edge of the sulcus or mouth, and also the tendency to a multicellular condition seen in the "chains" of Ceratium and the two-, four-, or eight-celled "somatella" of Polykrikos, suggest that "pelagic Dinoflagellata may have given rise

to simple pelagic Cœlenterates in which cell boundaries and cell layers may have played only a secondary and belated part as the size of the organism increased."

The economic importance of these organisms is great, both as a food supply and also occasionally as a destructive agency. It is well known that they form a large percentage of the stomach contents of sardines and other small fish. At times they are the dominant forms of the plankton, and have been recorded by Kofoid as the cause of outbreaks of "red water" on the Californian coast and elsewhere which may be a menace to the health and life of slow-moving or bottom-living animals which, being unable to escape from the infested area, die in quantity and are cast up in masses on the shore. Such discoloration of the water, due to species of Gymnodinium and Gonyaulax, are recorded as extending sometimes (August, 1917) for a hundred miles or more along the coast.

To point out a few slips in such a splendid memoir may seem ungracious, but Prof. Kofoid would probably prefer to have friendly criticism: In the phylogenetic diagram on p. 84, have not Protodinifer and Oxyrrhis exchanged places, should not Protodinifer be Pelagorhynchus, and, near the top of the diagram, should not Nematopsis be Nematodinium? The text-figure on p. 509 is evidently printed upside down, and in Fig. F (p. 30) the numbers 2, 3, and 4 are misplaced. Some of the references to figures in the text are not correct, but the careful reader will notice these for himself and will readily discover what is intended.

So many species are described, redescribed, or discussed, and the synonymy and history are given so fully, that the memoir is truly a monograph of the group, and will be found indispensable by all who work at these important lower organisms.

W. A. HERDMAN.

The Theory of Probability.

A Treatise on Probability. By J. M. Keynes. Pp. xi + 466. (London: Macmillan and Co., Ltd., 1921.) 18*s*. net.

DR. KEYNES'S book is a searching analysis of the fundamental principles of the theory of probability and of the particular judgments involved in its application to concrete problems. He adopts the view that knowledge may be relevant to our rational belief of a proposition without amounting to complete proof or disproof of it, and treats the probability as a measure of this relevance. Otherwise he does not attempt to define "probability," regarding it as a concept intelligible without further definition. In this respect, as in several others, he is in agreement with the views expressed by Dr. Wrinch and the present reviewer (*Philosophical Magazine*, vol. 38, 1919, pp. 715–31), and some comparison of the two presentations may not be out of place.

Previous writers have practically all assumed that probabilities can be expressed by numbers, and this assumption was put into precise form in the paper mentioned. Dr. Keynes departs completely from tradition on this point. Defining an "argument" as the process of passing to knowledge about one proposition by contemplation of it in relation to another of which we have knowledge, he denies not only that the probabilities of all arguments can be expressed by numbers, but also that they can be arranged in a one-dimensional series at all. Thus the probability of one argument may be neither greater than, equal to, nor less than that of another. The difference in actual application between this theory and ours appears likely to be slight, for the definitions and hypotheses are such that practically any two probabilities that one needs to compare are comparable. From these the formal theory is soundly developed.

The principle of non-sufficient reason, or indifference, asserts that we assign equal probabilities to propositions if we have no reason to do the contrary. The author criticises severely many previous applications of this principle (so severely that an unprepared reader is likely to be betrayed into expecting him to reject the principle altogether). He finally modifies it by saying that neither of the propositions deemed equally probable may be expressible as the disjunction of two mutually inconsistent propositions, of the same form as itself, and both consistent with the data. His precise statement of this important principle makes it possible to evaluate a large class of probabilities that could otherwise be only estimated, and is a most useful advance.

Dr. Keynes rejects definitely the view of Jevons and others that if any two alternatives are exhaustive and mutually exclusive, and we have no reason to prefer one to the other, the probability of each is $\frac{1}{2}$. His reasons for believing that this view leads to contradictions, however, appear incorrect. He says on p. 43: "If, for instance, having no evidence relevant to the colour of this book, we could conclude that $\frac{1}{2}$ is the probability of 'This book is red,' we could conclude equally that the probability of each of the propositions, 'This book is black' and 'This book is blue,' is also $\frac{1}{2}$. So that we

are faced with the impossible case of *three* exclusive alternatives all as likely as not." It appears to us that each of these estimates is based on different evidence, and, therefore, that it is quite possible that the sum of the probabilities should be greater than unity. A person who could recognise only one colour, say, blue, all others appearing alike to him, would estimate the probability that the book is blue at $\frac{1}{2}$. A person who could recognise only red would make a similar estimate for red. But one who could distinguish red, blue, and black, and no others, would estimate each as having a probability of $\frac{1}{3}$. In each case we follow the author in assuming no previous knowledge of the proportions of different colours among books.

The point is worth insisting upon, for we believe that the author has for such reasons refrained from estimating prior probabilities in many cases where such estimates would have been useful. In his discussion of sampling inference, for instance, he refuses to admit that any plausible estimate of the probable composition of a sample can be made, however large a sample has already been examined, unless we have further evidence that no disturbing cause exists. Admittedly the inference depends on the prior probabilities of different compositions, but we have shown that in ordinary cases a wide range of variation of the prior probability produces little variation in the inference made with regard to the composition of a large sample, and we think this is the only justification required. The acquirement of knowledge about a disturbing cause provides additional data and is valuable for that reason; its absence is no reason for denying a probability inference not based on it.

The author's insistence on the desirability of careful testing of the sample to see whether different subclasses from it have compositions similar to the whole is, however, very important on other grounds, for his careful discussion indicates the precise usefulness of a kind of additional information that is often obtainable and valuable. His conclusion (p. 426) that "sensible investigators only employ the correlation coefficient to test or confirm conclusions at which they have arrived on other grounds" is an exaggerated statement, but perhaps a salutary one.

A form of the frequency definition is discussed and rejected on the ground that it does not give any basis for induction. According to this the probability of a proposition p on evidence q is to be obtained by selecting a large number n of instances of q. If m of these are also instances of p, the probability of p given q is defined to be m/n. This theory is taken too seriously; it would be sufficient objection to point out that, unless m/n is 0 or 1, the probability would necessarily be changed by having $n+1$ instances instead of n, and would therefore be conventional. In the form of the frequency theory discussed (and also rejected) in our paper the probability is defined as the *limit* of this ratio when n tends to infinity. This view, though it has been seriously advocated, is not mentioned by the author.

The faults attributed to the book above are all on the side of excessive caution, and the positive contributions are extremely valuable. It is clearly written, with a good index and a copious bibliography. The misprints are few. Whitehead and Russell's "Principia Mathematica" is, however, mentioned a few times as if it were by a single writer. The work should be read by every student of science who aims at a real understanding of his subject.

HAROLD JEFFREYS.

The Royal Society Catalogue.

Catalogue of Scientific Papers, Fourth Series (1884–1900). Compiled by the Royal Society of London. Vol. 17, *Marc–P*. Pp. v + 1053. (Cambridge: At the University Press, 1921.) 9*l*. net.

THE high standard set by the volumes already published in this series is fully maintained in the seventeenth volume of the Royal Society's "Catalogue of Scientific Papers." The work of preparing the material for the press and of proof-reading was carried out by Miss Vagner and Miss Barnard, and until December 1920 Miss Chapman was also engaged upon the work. The Cambridge University Press is to be congratulated on the typographical excellence of the volume, the small type which had to be used being quite easy to read.

The papers indexed are those published during the seventeen years 1884 to 1900 by authors whose names begin with the four letters M (from Marc onwards), N, O, and P. No less than 10,662 names are indexed, the number of separate papers being 57,474. Thus, on an average, each author has published one paper every three years. The volume brings up the total number of authors' names already printed for the period 1884–1900 to 49,750, and the total number of entries of papers published by authors whose names begin with letters from A to P inclusive to 279,902. The catalogue of papers by authors whose names begin with letters from Q to Z is still to be published.

The Committee say that the difficulties in the printing and publishing trade, which for a time delayed the regular delivery of proofs, have now been overcome, so that they look forward with

F

confidence to an early completion of the remaining volumes. When these are published the gap between the "Catalogue of Scientific Papers" and the "International Catalogue of Scientific Literature" will be filled so far as the index of authors' names is concerned; the indexing of scientific papers under authors' names will then be complete up to 1914.

There will still remain the subject-index, of which we believe only the volumes for mathematics, mechanics, and physics have been published, and that some fourteen volumes have yet to appear. To most of us a subject-index is much more useful than an author-index. While an author-index is essential as a permanent record of work done by individual authors, it will be of little use to an investigator anxious to discover what has previously been done in a particular line of research. For such a purpose a subject-index is required. We therefore hope that the Royal Society will proceed with the production of subject-indexes for the period 1800–1900 on the plan already begun with such success.

In addition to the surname of the author, the "Catalogue of Scientific Papers" gives the full Christian names so far as these can be ascertained. This is not merely in order to give credit to those to whom it is due, but also to make it easy for those who refer to the catalogue to distinguish between an acknowledged master of a subject and a little-known author who may chance to have the same surname. We commend the printing of titles in the original language, followed, when necessary, by an English translation. Those who have attempted to render a foreign language into English know how difficult it is to convey the exact meaning of the author; it is better, therefore, to let him speak for himself. In some of our abstracting journals we may find titles of foreign papers not only translated but so altered that no one could reconstruct the original. Nevertheless we think the compilers of this volume would have done well to add the English equivalent of some of the titles which they have printed without a translation. This would apply, for example, to many papers published in Swedish.

The Royal Society, representing, as it does, all branches of science, is clearly the body best able to carry to a successful issue any work indexing the whole field of science; all who take an interest in science will therefore feel that they owe the Society a debt of gratitude for having undertaken the great work of making a complete catalogue of the scientific papers published during 1800–1900 and for showing its intention to continue the work to a successful issue. A monumental work of this kind will never be out of date, but will be treasured as a permanent record of the marvellous achievements in the domain of science during the nineteenth century.

Our Bookshelf.

Handbuch der biologischen Arbeitsmethoden. Edited by Prof. Dr. Emil Abderhalden. Abt. 5, *Methoden zum Studium der Funktionen der einzelnen Organe des tierischen Organismus.* (1) Teil 3, Heft 1, *Entwicklungsmechanik.* Pp. 218. 66 marks. (2) Teil 3, Heft 2, *Entwicklungsmechanik.* Pp. 219–440. 72 marks. Abt. 9, *Methoden zur Erforschung der Leistungen des tierischen Organismus.* (3) Teil 1, Heft 1, Lieferung 34, *Allgemeine Methoden.* Pp. 96. 30 marks. (Berlin und Wien: Urban und Schwarzenberg, 1921.)

(1) The five articles which form this "Heft" are concerned with the technique of experimental embryology. In his account of micro-surgery Prof. Spemann deals with the operations for the examination of eggs—for dividing them either incompletely, *e.g.* by means of a looped hair, or by actually cutting the egg into two—with transplantation of parts of embryos to unusual positions, etc. Prof. Barfurth discusses the technique for the inquiry into heteromorphosis and regeneration in various groups of animals—embryos as well as adults. In this part Fig. 48 is printed without reference letters or description. Prof. H. Przibram gives methods for investigating the influence on development of heat, light, gravity, etc.; Dr. Karl Herbst deals with the methods of modifying development by means of various salts in solution, and Dr. Neumayer describes the instruments and technique of a number of operations. The work forms a useful source of reference for research workers and advanced students who desire to ascertain the methods which have been most successful in practice.

(2) The memoir by Prof. Rhumbler deals with the methods of imitating or producing "models" of living processes by physical devices—*e.g.* amœboid movement, the ingestion of food as by an amœba, the formation of a test as in the Rhizopoda, cell-division, fertilisation, etc. The volume is a helpful and concise contribution to the literature of the physics of vital phenomena.

Both these parts would have been improved if they had been provided with an index or a table of contents.

(3) In this, the first article of a new volume, Prof. Przibram gives many useful suggestions as to the methodical beginning and carrying through of research in experimental zoology. The selection and clear statement of the problem to be attacked, the economical use of living specimens —and also of time—by carrying out, wherever possible, more than one line of research on the same

material, care in labelling all specimens—on these and other cognate matters the author draws from his extensive experience, and the article is one in which those who are beginning research will find much that is helpful.

Municipal Engineering. By H. Percy Boulnois. (Pitman's Technical Primers.) Pp. vii+103. (London: Sir Isaac Pitman and Sons, Ltd., 1921.) 2*s*. 6*d*. net.

IT is clear from the matter in this little book that the author has had very extensive experience in municipal engineering, and the list of important appointments he has held—as noted on the title-page—gives ample confirmation of this impression. He is therefore usually a safe guide in the matter of offering advice to young men who intend to enter this profession. The position, appointment, and training of the municipal engineer are explained, and the special responsibilities he has to accept are fully discussed. A considerable number of examinations have to be passed; these provide, or should provide, evidence of a sound training in the scientific and other subjects required of the municipal engineer. It is, therefore, unfortunate that the author, whilst decrying "cramming," suggests on p. 44 that there are numerous coaches or crammers who can assist a candidate. We should rather have expected advice of a kind which would have led young men to spend a few years in following a course in engineering with special attention to municipal engineering. Such courses are now available at several colleges, and when combined with a pupilage for the sake of acquiring practical experience will produce properly qualified men. That the author fully understands this is clear from other pages in the book, and it is unfortunate that the blemish on p. 44 should appear in this otherwise excellent and helpful volume.

History of the Great War, based on Official Documents. By Direction of the Historical Section of the Committee of Imperial Defence: Naval Operations. By Sir J. S. Corbett. Vol. 2. Pp. xi+448+17 plans. (London: Longmans, Green, and Co., 1921.) 21*s*. net.

THIS volume, the second of Sir Julian Corbett's masterly series on the naval operations of the great war, covers the six months from November, 1914, to May, 1915. It is based primarily on the official documents of the British Admiralty, but the information supplied by these has been supplemented from other sources, notably the revelations of disillusioned German seamen, such as Admiral Scheer and Admiral Hugo von Pohl. The narrative is fascinating in its interest. It displays in their entirety the operations of which at the time of their happening we obtained but partial glimpses. Here we can read—and, if we once start, must continue to read—about the raid on Scarborough and Hartlepool (December, 1914), the loss of the *Formidable* (January, 1915), the early attacks on the Dardanelles (February, 1915), and the sinking of the *Lusitania* (May, 1915). The maps and plans are numerous and excellent.

A Sketch-map Geography: A Text-book of World and Regional Geography for the Middle and Upper School. By E. G. R. Taylor. Pp. viii+147. (London: Methuen and Co., Ltd., 1921.) 5*s*.

A SERIES of sketch-maps presenting the fundamental geographical facts of regions and places, with brief explanatory text. The author claims three advantages for this method. In his first claim, that pupils will acquire the habit of working out the geography of a place for themselves, instead of reading up the facts, we think that he is over-sanguine. Boys, at any rate, will just learn up his sketch-maps by heart as they formerly did the written facts. Probably, however (as he claims next), they will remember these facts better, and will find the diagrams more interesting than solid paragraphs. Also the third advantage may be realised—the pupils will become accustomed to illustrate their work with sketch-maps, and this is an excellent habit.

The book is in itself too "sketchy" for a youthful student. It is meant to be used in conjunction with a good atlas, but should also be supplemented by a more detailed text-book. It may then be a valuable aid to teachers.

Pneumatic Conveying. By E. G. Phillips. (Pitman's Technical Primers.) Pp. xii+108. (London: Sir Isaac Pitman and Sons, Ltd., 1921.) 2*s*. 6*d*. net.

PNEUMATIC conveying is one of the so-called labour-saving devices, the usefulness of which has been recognised only comparatively recently. In the little book under notice Mr. Phillips sets forth the principles underlying the construction of pneumatic conveying systems and gives an account of some of the various uses to which this means of transport can be adapted. The first portion of the book deals with the different systems in use, and pumps, dischargers, pipe lines, suction nozzles, and other details of the necessary plant are described. Then follow chapters on grain and coal-handling plants and on the induction and the steam-jet conveyor. The concluding chapter recounts some of the multitudinous uses to which this extraordinarily adaptable and flexible method of transport can be put.

Small Single Phase Transformers. By Edgar T. Painton. (Pitman's Technical Primers.) Pp. x+95. (London: Sir Isaac Pitman and Sons, Ltd., 1921.) 2*s*. 6*d*. net.

THE scope of this practical little volume is sufficiently indicated by the sub-title, "Explaining a Commercial Method of Design. Making Possible Economy of Material and Accurate Predetermination of Characteristics, and Giving Information Enabling the Amateur to Design and Construct a Transformer Meeting his own Requirements." The same attention does not appear to have been given hitherto to effecting economies in the design of very small transformers as to that of large apparatus, and the author's way of attacking the problem should prove of use in this respect.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Fossil Buttercups.

It is remarkable, as Prof. Cockerell points out in Nature of January 12, p. 42, that until his discovery of a Miocene buttercup no species of the family Ranunculaceæ should have been recorded among the fossil plants of North America. More especially is this the case because the carpels of Ranunculus are among the commonest fossils found in deposits of Pleistocene and Pliocene age in Britain and the neighbouring parts of the Continent. Among the many lists of fossils determined by my husband and myself from such deposits, in one only, the Pliocene of Bidart (Basses-Pyrénées), is the genus not represented, and in this deposit very few species of any kind were found.

The oldest carpel I have seen is that of an extinct batrachian Ranunculus (*R. gailensis*, E. M. Reid), very thick-walled and globose, from the base of the Pliocene of Pont-de-Gail (Cantal). From the same horizon, but another locality in Cantal, M. Pierre Marty recorded *R. atavorum*, Sap., which he considers nearly related to *R. fluitans*. It is quite probable, though it has not been proved, that carpel and leaf belong to the same species.

In the latest Pliocene of the Cromer Forest-bed, with the exception of two undetermined carpels, all are British species. In the Upper Pliocene of Tegelen (Holland) *R. aquatilis* and *R. repens* are found associated with *R. nodiflorus*, a species of Central Europe and the Orient, and with a single specimen of a peculiar form of *R. sceleratus* found more abundantly at Castle Eden. In the Middle Pliocene of Castle Eden no definite West European species is found, though the form of *R. sceleratus* already mentioned and a peculiar batrachian Ranunculus, both probably extinct, occur associated with two Central European species, *R. nodiflorus* and a varietal form (perhaps extinct) of *R. lateriflorus*, also an extinct species of which the affinity has not been discovered. In the Lower Pliocene of the Dutch-Prussian border the only West European species is *R. nemorosus*; it occurs associated with *R. nodiflorus*, *R. lateriflorus*, var., and the South European species *R. brutius*. In the lowest Pliocene of Pont-de-Gail one specifically indeterminable carpel and the batrachian *R. gailensis*, already referred to, were found.

Among the hundreds of Pleistocene and Pliocene specimens examined none has shown indications of two seeds, but I have not been able to carry the record of the genus so far back as Prof. Cockerell.

In the work here referred to the carpels were in every case obtained by "washing" the material and sieving away the matrix. Were this method applied to some of the North American Pleistocene and Tertiary deposits I should anticipate that they might yield, not only abundant carpels of Ranunculus, but the fruits and seeds of many other herbaceous plants.

Eleanor M. Reid.

Pinewood, Milford-on-Sea, January 23.

The Accuracy of Tide-predicting Machines.

In the article in Nature for November 24 last appearing under the title "British Research on Tides" there occurs a statement which may, perhaps, leave an erroneous impression with those not familiar with tide-predicting machines. The statement in question—"a test of the accuracy of the tide-predicting machines used by the Admiralty and the India Office has indicated some serious errors in their results, and it is concluded that the labour of reading the curves afforded by the machines, with any pretence to accuracy, is comparable with the labour of direct computation, while the value of the results is greater in the latter case"—although made definitely with reference to particular tide-predicting machines, might, nevertheless, leave the impression that tide-predicting machines in general were subject to "serious errors in their results." It therefore appears of value to discuss briefly the subject of the accuracy of tide-predicting machines and to refer to some tests made with a direct-reading type of tide predictor.

Tide-predicting machines, or tide predictors as they are frequently called, make use of the harmonic tidal constants, and are contrived for the purpose of summing a number of terms of the form $A \cos(at+\alpha)$, in which for each harmonic constant A is the amplitude, a the speed per unit time t, and α the initial phase. For any given port, therefore, the height of the tide at any time is the instantaneous sum of the simple constituent tides represented by the harmonic constants. And in the tide predictor this instantaneous summation is effected by means of a flexible chain which passes alternately over and under a series of pulleys the motion of each of which represents the changes in elevation of a particular simple tide.

The accuracy of a tide predictor is therefore to be measured by the accuracy with which it sums the simple constituent tides represented by the harmonic constants. It is necessary to emphasise this, for not infrequently one meets with the assumption that the accuracy of the tidal predictions tests the accuracy of the tide predictor. Tidal predictions are the product of the tide predictor, and for any given port aim to give in advance the times and heights of high and low water. And the test of the accuracy of these tidal predictions is, obviously, the closeness of agreement with the tides as they actually occur.

It is to be noted, however, that the times and heights of the normal or predictable tide are subject to the disturbing effects of variations in wind, atmospheric pressure, rainfall, and seiche. Hence, altogether apart from any imperfections in the tide predictor or in the harmonic analysis which separates out the simple constituent tides, tidal predictions may differ from the observed times and heights of the tide, due to the disturbing effects just mentioned, the times of occurrence of which cannot be foreseen at the time the tidal predictions are made. It is, therefore, obvious that, while in a measure the accuracy of the tidal predictions tests all the processes entering into their making, it does not strictly test the accuracy of the tide predictor.

Tide predictors are of two types, which we may denominate respectively as curve-tracing machines and direct-reading machines. In the former there is traced, to a suitable scale on a sheet of paper, a curve of the predicted tide from which the height of the tide at any given time or the times and heights of high and low water may be scaled. In the direct-reading tide predictor the height of the tide at any time, and also the times and heights of high and low water, are indicated on dials from which they are read off directly.

It is obvious that the prediction of tides can be carried out more rapidly with a direct-reading tide predictor than with the curve-tracing type, for reading figures from two or three dials is less time-consuming than scaling these same values from a curve. But

even apart from its greater economy in time, the direct-reading machine has a still further advantage in that it is possible to secure more accurate results than with the use of the curve-tracing type. The dials on the direct-reading tide predictor are graduated to single minutes and to single tenths of a foot; it is, therefore, not difficult to estimate to within half a minute or five hundredths of a foot. To estimate as closely from a curve drawn to a moderate time-and-height scale is well-nigh impossible.

Since the tide predictor sums a number of continuous functions, it cannot be made to give the exact results of an adding or a multiplying machine. And because of the large number of moving parts that enter into the construction of a tide predictor, we cannot hope to secure the accuracy that may be obtained with a planimeter. In fact, the errors of the tide predictor may be ascribed almost wholly to the varying tensions on the numerous moving parts, but it appears that these errors should not be large enough to be serious.

In 1910 the U.S. Coast and Geodetic Survey put into operation a direct-reading tide predictor which had been constructed in its instrument division. Prior to the use of this machine for the prediction of tides for the annual tide tables it was carefully tested, one of the tests consisting in the comparison of the hourly heights of the tide as given by the machine and as computed analytically "by hand." The machine was set with 30 components for Hong Kong, China, January 1, 1912, and run through to December 31. For that day hourly heights of the tide were read off for the entire twenty-four hours.

At the beginning of this year, after it had been in use about twelve years, the machine was again set for Hong Kong, January 1, 1912, and run through to December 31, and the hourly heights read off. December 31 was chosen so that all errors due to the incommensurability of the speeds of the various components might accumulate. The table below shows the differences between the computed and the predicted heights:—

Hourly Heights of Tide, Hong Kong, China, December 31, 1912.

Hour	Predicted in 1910. Feet.	Predicted in 1922. Feet.	Computed. Feet.	Differences 1910. Feet.	Differences 1922. Feet.
0	4·28	4·30	4·32	−0·04	−0·02

It is to be noted that the height-scale on the tide predictor is graduated to tenths, so that the hundredths were estimated. The differences between the heights as predicted and as computed are relatively small, in no case exceeding 0·06 ft. It is also interesting to note the close agreement between the predictions made in 1910 and those in 1922, these predictions being made not only twelve years apart, but also by different persons. It is only proper to add that these predictions were undoubtedly carried out with more than ordinary care, owing to the psychological effect of the knowledge that a test was involved. Furthermore, it must be stated that with a single-component tide the accuracy attained was not so gratifying as in the example given above, the reason being that with a number of components there are compensating tensions of the moving parts, while with a single component there are no such compensations. It is to be borne in mind, however, that in the prediction of tides there is always a considerable number of components involved.

It would be unfortunate if the impression that tide predictors are subject to serious errors gained currency, for, apart from the use of such machines for the prediction of tides for the tide-tables, there are numerous tidal problems involving time-consuming computations which may be very easily made with the tide predictor. In the elimination of the effects of short-period tides on daily mean sea-level, in the computation of the changes in sea-level due to tides of long period, in the elimination from the observed tide of the tide due to a number of constituents, and in similar problems, the tide predictor should very materially lessen the laborious computations involved.

H. A. MARMER.

U.S. Coast and Geodetic Survey, Washington, D.C., January 5.

THE errors found in the British tide-predicting machines referred to in the article were more serious than those described by Mr. Marmer. The machines were of the curve-tracing type, and therefore inevitably less accurate (with the time and height scales ordinarily used) than direct-reading machines; they had zero errors, and also diminished the apparent range of the tide. The direct-reading machine used by Mr. Marmer is both more accurate and quicker in use; for many purposes, though perhaps not for all, such a machine is a valuable substitute for numerical computation.

The Oxidation of Ammonia.

THE following details of the early history of the oxidation of ammonia, a process which became of great importance during the war, do not appear generally to be known, and may be of interest. The first clear statement of the oxidation of ammonia which I have seen is contained in a paper by the Rev. Isaac Milner, B.D., F.R.S., president of Queens' College, Cambridge, published in the Philosophical Transactions for 1789 (vol. 79, pt. 2, pp. 300–13), and republished in Crell's *Annalen* (1795, pt. 1, pp. 550–62). The title of the English paper is "On the Production of Nitrous Acid and Nitrous Air," and the German paper is a translation, in which "nitrous acid" is rendered "Saltpetersäure" and "nitrous air" (*i.e.* nitric oxide, NO) "Saltpeterluft."

Milner remarks that, although the relation between nitrous acid and the volatile alkali was known, there was no known case in which the latter was used in the production of nitrous acid or nitrous gas. In

March, 1788, he tried the experiment of fitting a retort containing caustic volatile alkali to a gun-barrel filled with crushed pyrolusite (maganese dioxide), and heating the latter to redness, whilst the retort was also heated. Signs of nitrous acid and nitrous air soon made themselves manifest, and by continuing long enough nitrous gas was obtained. The experiment was repeated many times; its success depended on the nature of the pyrolusite, the temperature of the furnace, and the patience of the experimenter. Full details are given as to the best way of carrying out the experiment. It frequently happens that the ammonia passes over unchanged. Red lead was found, unexpectedly, not to be active, but green vitriol burnt white gave better results.

The changes are correctly explained by Milner as due to oxidation. With burnt alum he obtained the curious result of the evolution of a large amount of inflammable gas mixed with hepatic air (sulphuretted hydrogen) and sulphur, whilst sulphur remained in the gun-barrel. It is, therefore, not sufficient merely to bring the volatile alkali in contact with a substance containing dephlogisticated air, but another substance is also necessary which has a strong attraction for the combustible substance.

It is also noteworthy that Black in his "Lectures on Chemistry" (edited by John Robison, Edinburgh, 1803) states that "our newspapers inform us that the French chemists procured saltpetre for the Army by blowing alkaline gas, and even putrid steams, through red-hot substances which readily yield oxygen" (vol. 2, p. 245); and there is a statement that "Mr. Milner of Oxford (*sic*) published a paper in the 79th volume of the Philosophical Transactions . . . but he did not attempt to ascertain how much of the nitrous acid might be produced from a limited and known quantity of the volatile alkali" (vol. 2, p. 455). Black (*ibid.*) gives a clear explanation of the process; the ammonia "is a compound of hydrogen and azote, we need only suppose that part of it is totally decomposed and destroyed by the action of the oxygen contained in the manganese. Part of it, uniting with the hydrogen, forms water or watery vapour; and part, uniting with the azote, forms vapours of nitrous acid." I have not traced the reference to the "newspapers," but a footnote on the same page (455) reads: "*January*, 1796. There is a rumour that the French have manufactured saltpetre, during a part of the war, by obtaining nitrous acid from the vapours of volatile alkali, forced to pass through red hot manganese. Author."

Many strange names have of late been given to the process of ammonia oxidation; we have heard of the "Ostwald-Mittasch process" and others. The first use of platinum as a catalyst appears to be due to Kuhlmann, of Lille, in 1839.

A Specimen of Wrought-iron Currency from the Kisi Country, Sierra Leone Protectorate, West Africa.

A SPECIMEN of iron currency from the Kisi country was obtained by one of us (E. R. M.) while on service in West Africa in 1915 through the agency of his servant, Ali Badara, the son of a chief in the adjoining Momo-Fullah country; and a description of it may be of interest to readers of NATURE.

As this form of currency ceased to be used after the establishment of the British Protectorate in 1787, the age of the specimen may be estimated at not less than 130 years, and probably more.

The "coin" (Fig. 1) is of rough workmanship, and consists of a strip of roughly forged rectangular section, one half being twisted and the ends hammered out into thin blade-like projections, the broad end serving to prevent the "coin" slipping through the belt in which it is carried.

Analysis shows the metal to be wrought-iron of good quality, probably made by the direct process of reducing an oxide ore by carbon in presence of a basic slag containing much iron oxide to prevent carburisation of the iron, most of the slag then being

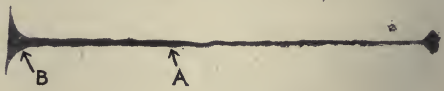

FIG. 1.—Photomicrograph × 1/5.

expressed by hammering the pasty mixture of iron and slag. The percentage composition is as follows: Carbon, 0·095; silicon, 0·103; manganese, nil; sulphur, 0·024; and phosphorus, 0·046. For the analysis drillings were taken from the wider part of the specimen and fragments from the narrow end. These were washed in benzene to remove the coating of black grease from the surface of the metal.

The metal is extremely soft and easily bent, the Brinell hardness at the point A being 121 (using a

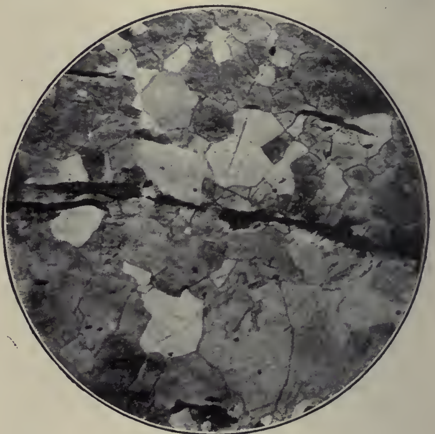

FIG. 2.—Photomicrograph × 275.

ball 1 mm. diameter and a load of 10 kilograms). A small fragment was cut from the point B, embedded in solder, polished, etched with 2 per cent. nitric acid in alcohol, and photomicrographed. The photomicrograph (Fig. 2) shows the typical crystalline structure of a pure iron, together with elongated inclusions of slag.

Molecular Structure of Amorphous Solids.

A QUESTION of fundamental importance in the theory of the solid state is the nature of the arrangement of the ultimate particles in amorphous or vitreous bodies, of which glass is the most familiar example. Is it to be supposed that the molecules are packed

together at more or less uniform distances apart, as in crystals, the orientation of individual molecules or of groups of molecules being, however, arbitrary? Or, on the other hand, is the spacing of the molecules itself irregular, the solid exhibiting in a more or less *permanent form* local fluctuations of density similar to those that arise *transitorily* in liquids owing to the movement of the molecules? The physical properties of amorphous solids, notably their softening and viscous flow below the temperature of complete fusion, would tend to support the latter view, but the possibility of a closer approximation to the crystalline state should not entirely be ruled out, especially in view of the very interesting recent work of Lord Rayleigh on the feeble double refraction exhibited by fused silica (Proc. Roy. Soc., 1920, p. 284). A good deal might be expected to depend on the nature of the material, its mode of preparation, and heat treatment. A material formed by simple fusion and re-solidification of comparatively simple molecules, such as silicon dioxide, might stand on a different footing from a material such as ordinary glass built up by chemical action and formation of complex silicates.

If the arrangement of molecules in a vitreous body were irregular, the local fluctuations of optical density would result in a strong scattering of a beam of light passing through it, the intensity of such scattering being comparable with that occurring in the liquid state at the temperature of fusion of the material (see note by the present writer in NATURE of November 24 last, p. 402). On the other hand, if the arrangement of the molecules approximated to the crystalline state the scattering of light would be merely that due to the thermal movements of the molecules and would be much smaller. As a matter of fact, glasses exhibit a very strong scattering of light, some 300 to 500 times as strong as in dust-free air, the Tyndall cone being of a beautiful sky-blue colour and nearly, but not quite, completely polarised when viewed in a transverse direction. (Some glasses exhibit a green, yellow, or pink fluorescence when a beam of sunlight is focussed within them, and cannot be used for the present purpose; the fluorescence, even when very feeble, can be detected by the difference in colour of the two images of the Tyndall cone seen through a double-image prism.) Rayleigh, who observed the light-scattering in glass, attributed it to inclusions, some of which he assumed must be comparable in size with the wave-length (Proc. Roy. Soc., 1919, p. 476). The closest scrutiny through the microscope under powerful dark-ground illumination fails, however, to indicate the presence of any such inclusions, and it seems more reasonable to assume, in view of the foregoing remarks, that the scattering is really molecular. Its magnitude is of the order that might be expected on the basis of a non-uniform distribution of the molecules.

Further observations with specially prepared glasses and with fused silica would be of great interest to investigate the influence of the chemical constitution and heat treatment on the molecular *texture* of the solid.

Forecasting Annual Rainfalls.

IN NATURE of September 1 last, p. 12, in commenting on the remarkable rainfall at Blue Hill Observatory, Mass., in July, 1921, departures from mean monthly amounts were given to show that the locality was experiencing a period of excess of rainfall. Furthermore, it was intimated that the annual amount for 1921 would exceed the 35-year normal by 150 mm. (5·90 in.). The excess actually was 136 mm. (5·35 in.) and practically a verification.

Many things must be considered in forecasting annual rainfalls, even after the year is well advanced, and no one appreciates the uncertainties better than the professional forecaster. All forecasting is hazardous, but weather forecasting is especially so.

Perhaps the most important factor in estimating the seasonal trend is the strength and location of the North Atlantic infrabar (the "centre of action" of Teisserenc de Bort).

In "The Winds of Boston" (Harvard College Observatory Annals, vol. 73, pt. 3, and vol. 83, pt. 1) the relation between surface-flow of the air and rainfall is given in some detail. A preponderance of east and south-east winds is evident during a rainy season.

The rainfall of 1921 supports the views there given. There was a marked deficiency of west-north-west wind and a marked excess of north-east to south-east wind. The average durations, 37-year normal, are: West, 1708 hours; north-west, 1543 hours; and north, 835 hours. In 1921 these values were decreased 14 per cent., 34 per cent., and 20 per cent. The excess of east wind is even more noticeable. Average durations are: East, 617 hours; south-east, 560 hours; and north-east, 838 hours. The deficiencies were: East, 57 per cent.; south-east, 47 per cent.; and east, 27 per cent.

A just estimate of the character of a season or of a year cannot be based absolutely on the quantity or duration of rain. One torrential rain lasting a few hours can offset weeks of rainless weather. At Blue Hill, fortunately, such occurrences are rare.

A striking illustration of the untrustworthiness of rainfall as a criterion of season is found in the recent flood in Texas. At Taylor, on September 9, 1921, following two months of drought, there was a rainfall of 587 mm. in twenty-four hours. This is the greatest daily rainfall yet reported in the United States following two months without any rain. This city had as much rain in one day as London gets in a year, yet the mean annual rainfalls of the two localities are not markedly different, being 620 mm. for London and about 970 mm. for the Texas city. Note that the latter locality received 60 per cent. of an annual rainfall in twenty-four hours. Such an accidental fall must be eliminated, or any effort to correlate pressure distribution, surface flow, and rain becomes futile. Furthermore, it would seem that efforts to link up variation in solar output and seasonal conditions as determined by the amount of rain are open to question.

Units in Aeronautics.

THE present writer's original letter was phrased with scrupulous care to limit consideration to the single proposition that consistency cannot be maintained in dynamical equations if gravity units are used in expressing inertia forces, in particular not by merging explicit g in the slug. An example was given so conclusive as to elicit, it was hoped, Prof. Bairstow's own explanation of the statement cited from his text-book.

No opinion was then offered on the validity of the relation $R = k\rho SV^2$, or on the merits of the poundal and dyne. The courtesy of this column would scarcely stretch to the detailed statement of the writer's position in respect of opinions attributed to him by implication on these and other apparently digressive points raised by Mr. Rowell and Sir George Greenhill.

A. R. LOW.

Some Problems of Long-distance Radio-telegraphy.[1]

By DR. J. A. FLEMING, F.R.S.

I.

THE achievement of transatlantic radio-telegraphy in 1901 and 1902 was of interest to physicists chiefly by reason of the fact that they did not see clearly why it should have been possible at all. The mystery of it was increased when at later dates radio signals were transmitted a quarter of the way round the world, and finally, with high-power stations and thermionic valves detected even at the Antipodes.

The wave-length of the waves used in the earliest work at Poldhu was about 3000 ft. The earth, roughly speaking, is a sphere 42 million feet in diameter. Hence the ratio of wave-length then used to earth diameter was about 1 : 14,000.

In the case of light there is a small bending or diffraction of the wave round an opaque obstacle. In other words, there is some small amount of illumination within the boundary of the geometrical shadow. The average wave-length of light waves is about 1/2000th of a millimetre, and a sphere having a diameter of 7 mm. would be 14,000 of such wave-lengths. Now if an exceedingly small source of light were placed on the pole of a sphere 7 mm. in diameter in a dark region, it is certain that there would be no illumination at the equator of the sphere. In other words, there would not be any sensible diffraction at an angular distance of 90°. Modern long-distance radio-telegraphy conducted with waves of wave-length approximating to 10 miles or so can communicate even with the Antipodes.

The mathematical treatment of the problem of the diffraction round a conducting sphere of electric waves which are radiated from a transmitter at its pole consists in expressing the magnetic and electric forces at any angular distance θ in the form of a series of harmonic terms. It is in the summation of this series to obtain the integral effect at the receiver that the chief difficulties and differences of opinion occur, and most analysts have employed only an approximation. In 1918 Prof. G. N. Watson effected a new and complete summation which enables the value of the forces to be calculated for any point on an imperfectly conducting sphere.

The result of eighteen years' work on this problem by mathematicians of the highest rank has been to give us a formula for the current in a receiving aerial of given resistance determined in terms of wave-length, aerial heights, and distance which represents the result of pure diffraction acting round a spherical earth of perfect conductivity. On the other hand, when we come to compare the results of this diffraction formula with actual observations in practice we find an enormous discrepancy. The actual received currents in the case of long-distance stations for the usual sending aerial currents are hundreds of thousands, or even millions, of times greater than the received current predicted by the theoretical formula. Thus, to take a case quoted by Dr. Van der Pol from observations made at Darien Radio Station, on the Panama Canal, on radio signals sent from Nauen, near Berlin, Dr. L. W. Austin gives the following figures: $I_1=150$ amperes, $\lambda=9\cdot4$ km., $a_1h_1=120$ metres, $a_2h_2=146$ metres, $R_2=29$ ohms, and $d=9400$ km. Now the actual received current was $I_2=1\cdot3$ microamperes, but the value predetermined by the formula is only 0·6 of one millionth of a microampere. In other words, the actual received current in this case is two million times greater than the predicted current.

The upshot of the whole matter then is this: Long-distance radio-telegraphy, say, round one-quarter of the circumference of the earth, would certainly be quite impossible but for some cause, other than diffraction, operating to compel the waves to follow round the earth's curvature and not quickly glide off it.

Oliver Heaviside in 1900 suggested that an upper conductive layer on the atmosphere might act as a guide to the waves, radio-telegraphy being, in fact, conducted in a thin spherical shell of non-conductive air bounded by a conductive earth and a conductive upper air. He did not furnish any valid reasons to explain why this upper air conducts and how its conductivity is preserved, and although the suggestion has been very generally accepted by radio engineers, it has been taken without sufficient criticism of its difficulties and details. There has been in the intervening twenty-one years an immense accumulation of facts, all showing, however, that long-distance radio-telegraphy is conditioned by the physical constitution of our atmosphere and is very far removed indeed from being simple electromagnetic wave propagation in empty space. An important epoch in this connection is the year 1902, when Senatore Marconi discovered during one of his early voyages across the Atlantic in the s.s. *Philadelphia* in February, 1902, that radio signals from Poldhu could be received at night about thrice the distance they could be read in daytime, being detectable only up to 700 miles by day, but readable up to 2099 miles by night.

It was at once surmised that the difference was due to ionisation of the air by sunlight, which, by liberating electrons from atoms, gives to the air conductivity. It was some years before this vague suggestion was converted by Dr. W. H. Eccles into a more definite scientific theory, many speculations in the meantime being found wanting in adequate basis, such as that which regarded the sunlit air as having an absorption for the energy of electromagnetic waves similar to that of foggy or misty air for visible light.

[1] Abridged from two sections of the Trueman Wood lecture on "The Coming of Age of Long-distance Radio-telegraphy and Some of its Scientific Problems," delivered before the Royal Society of Arts on November 23, 1921. The complete lecture is published in the Journal of the Society for December 9 and 16, 1921.

Before entering into further discussions of the facts, it will be convenient to mention a few of the generally accepted views as to the constitution of the terrestrial atmosphere and its ionisation by light.

By the use of hydrogen-filled sounding balloons carrying self-recording meteorographs, it has been possible to explore the atmosphere up to a height of about twenty miles. One of the results is to show that our atmosphere may roughly be divided into two regions. In the lower layer, called the *troposphere*, the atmospheric gases are kept well mixed up by winds and convection. This layer extends to a height of six or seven miles or so, and in it the temperature falls regularly with increasing height at the rate of about 6° C. per kilometre of ascent until a temperature of about $-55°$ C. is reached. Above this is a zone called the *stratosphere*, of unknown thickness, in which the temperature remains constant. Above a height of about seven miles water vapour is absent, and at higher levels convection ceases to operate and the atmospheric gases arrange themselves in order of density. The outer and highest levels above a height of sixty miles (=100 km.) are chiefly composed of helium and hydrogen with possibly some small admixture of the rarer atmospheric gases neon and krypton.

The volume composition of the atmosphere at the earth's surface is as follows:—

Nitrogen ...	78·05 per cent.
Oxygen ...	21·00 ,,
Argon ...	0·93 ,,
Carbon dioxide	0·03 ,,
Hydrogen ...	1 to 10 vols. in a million of air.
Neon... ...	10 ,, ,,
Helium ...	1 to 2 ,, ,,
Krypton ...	1 vol. ,, ,,
Xenon ...	0·05 ,, ,, ,,

Oxygen is almost entirely absent at a height of 100 km., but nitrogen is still present in a rarefied form. The presence of hydrogen and helium at these high levels has been indicated by an observation of Pickering on the spectrum of a meteoric stone entering the earth's atmosphere, which showed the hydrogen and helium lines.

Next, as regards the action of light on the gases of the atmosphere. Light waves of high refrangibility impinging on nearly all substances, especially those containing electropositive atoms, liberate from them electrons. The atom is now considered to be a collocation of negative electrons arranged in concentric shells, possibly in orbital motion, round a central positively charged nucleus in which the gravitative mass of the atom chiefly resides. Light of short wave-length causes one or more of these negative electrons to be detached and projected with a high velocity. The more electronegative an atom is the higher must be the frequency of the light to affect it. The electrons so detached are called photo-electrons and the action photo-electric.

In the case of sodium or potassium, which are highly electropositive metals, photo-electrons are emitted under the action of visible light, about the middle of the spectrum, but for less electropositive metals—*e.g.* zinc and magnesium—the action takes place only with ultra-violet light. Hence it follows that a plate of zinc illuminated by light from an electric arc or by the spark between aluminium balls loses a negative charge readily, and if insulated, becomes positively electrified owing to the loss of negative photo-electrons. The velocity with which these photo-electrons are projected is considerable, and may be 500–1000 km. per sec.

For most metals the ionising potential is about two to four volts, hence the maximum wave-length of ionising light is just beyond the violet end of the visible spectrum. But for atmospheric gases, when pure and free from dust or moisture, the ionising potential is much higher, being approximately as follows:—

Nitrogen ...	7·5 volts	Argon ...	12 volts
Oxygen ...	9 ,,	Neon ...	16 ,,
Hydrogen ...	11 ,,	Helium ...	20·5 ,,

It follows from this that the atmospheric gases cannot be ionised by light of longer wave-length than 1350 Å.U. Rays of this short wave-length are not transmitted by quartz but only by certain samples of fluorite, and are absorbed by a very small thickness of air. No sunlight of shorter wave-length than about 2950 Å.U. reaches the earth's surface, as shown long ago by Huggins and Cornu.

Hence the conclusion is forced on us that pure dust-free atmospheric gases cannot be ionised at the lower levels of the atmosphere by the direct action of sunlight, but at the higher levels above 60 to 100 km. doubtless there is direct ionisation.

Nevertheless, ionisation does take place in the lower atmospheric levels, as shown by the small finite electric conductivity possessed by the air, which proves that there are negative ions, either free electrons, or electrons attached to neutral atoms, and also positive ions present in the air, even over wide oceans. Thus, Boltzmann found in tests made in mid-Atlantic 1150 positive and 800 negative ions per c.c. of air. A. S. Eve found 600 to 1400 positive and 500 to 1000 negative ions per c.c., the positive being slightly in excess.

This ionisation may be produced either by photo-electric action on dust or ice particles in the air, by radio-active matter in the soil, by photo-electric action upon complex gaseous molecules in the air, or generated by the light and called condensation nuclei. Such agencies, however, cannot account for the far larger and permanent ionisation necessary to give the required electric conductivity in the higher atmosphere if it is to act as a guide to long electromagnetic waves.

A consideration of the terrestrial radio-telegraph problem shows that if there is any conductive layer in the upper atmosphere which can act as a guide to long electromagnetic waves round the earth, it must possess the following properties:—

(1) It must be permanently ionised, which means that its ionisation must not vanish in the night-time since, so far as we know, its guiding powers are not suspended on the shadow side of the earth. This seems to imply that the ionisation must be predominantly of one sign or that the *plus* and

minus ions are so far separated that they do not readily recombine. True gaseous photo-ionisation always produces ions of both signs in equal number mixed up together, and the conductivity quickly disappears when the ionising agency is withdrawn.

(2) The resulting electric conductivity must be sufficiently high, say, as good as that of ordinary fresh water, to act as a true wave guide. This implies that the ions must be very numerous per c.c. and very mobile or have high ionic velocities under unit electric force.

Bearing in mind that the upper regions of the earth's atmosphere above the 100 km. level probably consist chiefly of hydrogen, and that the velocity of ions in hydrogen under unit electric force is, according to measurements, from two to three times that in oxygen or nitrogen at the same pressure, it is easily seen that in the upper hydrogen levels of the atmosphere a very moderate amount of ionisation, say, 10^7 ions per c.c., might give a conductivity of the order of that of fresh water, or about 700,000 ohms per c.c. Another quality this conducting layer must possess if it is to act as a true reflector of long waves is a somewhat sharply defined lower surface.

It has already been remarked that observations on signal strength over long distances show an enormous difference between the actual measured values and those predicted by a simple diffraction formula. Attempts have been made to find an empirical formula for the received current in terms of the other quantities involved. At first these efforts started with the erroneous assumption that the attenuation might be regarded as due to an "absorption" caused by the atmosphere, and therefore mathematically represented by an exponential factor appended to the simple Hertzian expression for the magnetic or electric force at a known distance on the equatorial plane of a small oscillator.

Prof. G. N. Watson finds that if in place of a perfectly conducting spherical earth in free space we assume an earth having a conductivity about the same as sea water, enclosed in a spherical sheath or shell of material having a conductivity of about $1{\cdot}44 \times 10^{-15}$ E.M.U., equal to a specific resistance of 700,000 ohms per c.c. or not far from that of ordinary fresh water, the interspace being about 100 km., then the diffraction formula for the receiving aerial current would have to be modified and the exponential factor becomes $\epsilon^{-9{\cdot}6\theta/\sqrt{\lambda}}$. Watson therefore considers that if we are able to assume an upper conducting layer in the atmosphere at a height of about 100 km. having a fairly sharp under-surface and a specific resistance of about 700,000 ohms or, say, 0·75 megohm per c.c., then guided wave propagation through the included spherical shell of insulating air would account for the observed attenuation in actual terrestrial long-distance radio-telegraphy.

We have then to consider what are the probabilities and possibilities for the existence at a height of 100 km. or so of such a conducting layer and how it may be supposed to become ionised. Gaseous conductivity is always and only due to the presence of ions, and in the above case these are created by the strong electromotive forces brought into play. In gases contained in glass vessels there are always some few free ions or electrons present for some reason. If a high frequency magnetic field is made to act on the gas these ions are driven with great force against the gas molecules and ionise them, thus producing very quickly a copious supply of ions and giving the gas high conductivity. We cannot, however, say that a rarefied gas is a good conductor *per se* for very feeble impressed electromotive forces as we can say that a metal is a good conductor. Hence mere rarefaction due to height will not bestow the required electric conductivity on the atmosphere. Neither can the required ionisation be produced by solar light, because then it would vanish in the night-time by recombination of the ions.

The suggestion I wish to make as to the cause of this ionisation is based upon a modification of hypotheses already advanced by S. Arrhenius, K. Birkeland, and W. J. Humphreys concerning the projection of dust by light pressure from the sun.

We know that the sun's photosphere is in a continual state of disturbance due no doubt to violent explosions in regions beneath this light-giving locality. Above this photosphere lies the so-called reversing layer composed of metallic vapours which produce the Fraunhofer lines in the spectrum. These eruptions carry up not only metallic vapours, but also vast masses of the superlying chromosphere composed chiefly of hydrogen and helium gases in the form of solar prominences or red flames which are often seen rising to a height of several hundred thousand kilometres in a few minutes, thus indicating velocities of several hundred kilometres per second. When these solar metallic vapours are thus carried up into colder regions they must be condensed into a metallic mist or rain composed of particles of various sizes. We know also from experiment as well as theory that light exercises a pressure on solid objects and that this pressure per square centimetre for totally absorbing or black bodies is numerically equal to the light energy in the cubic centimetre. Measurements made of the so-called solar constant at the earth's surface when corrected for atmospheric absorption give a value of 2·5 gram calories per sq. cm. per min. Hence the energy of light per c.c. is nearly $6/10^5$ ergs and the light pressure therefore $6/10^5$ dynes per sq. cm. on a black surface. But at the sun's surface this pressure is 46,000 times greater, or 2·75 dynes per sq. cm. As this pressure varies as the square of the linear dimensions of the particle whilst gravitation varies as the cube, it is clear that as the dimensions of a particle decrease a limit will be reached at which the light pressure will overbalance the gravitation attraction.

It is easy to prove from known data that at or near the sun's surfaces black particles of the density of water would be just repelled if they had diameters of 15,000 Å.U. $= 150/10^6$ cm.

If their density is 5·5, then the critical diameter

will be 2700 Å.U. If, however, the particles have diameters of only 1600 Å.U. and unit density the light pressure will be nineteen times greater than the gravitation attraction. For sizes still smaller the light pressure would decrease again, and for diameters less than 500 Å.U. gravity would once more preponderate.

If, then, the solar eruptions drive up into colder regions vapours which are condensed to liquid or solid particles, a sorting action will at once come into play. Particles above a certain diameter will be drawn back into the sun. Particles below a certain diameter will be repelled away with great force by light pressure, and particles of a certain critical diameter will remain suspended in space. The solar corona may perhaps be in part composed of solar dust of this critical diameter, as Arrhenius has suggested. Now, as regards that dust which is repelled by the sun, it is easy to calculate the time particles of certain sizes will take to travel to the earth's orbit and the velocities they will then possess. Taking the particles to have unit density and three sizes, viz. 1600, 5000, and 10,000 Å.U., and to be projected from the sun with velocities of 200 km. per sec., I find that the times required to travel to the earth's orbit will be respectively twenty-two hours, forty-two hours, and seventy-six hours. The velocities with which they will arrive will be 1700 km. per sec., 780 km. per sec., and 350 km. per sec. respectively.

These minute particles, composed, it may be, of carbon from the photosphere or metallic dust from the reversing layer or volcanic ash or other solar materials will in general carry electric charges. The high temperature will cause emission of electrons from the metallic particles, as also will the fierce ultra-violet radiation to which they are exposed. The metallic vapours will also be in a state of ionisation, and the free electrons emitted will condense round them gases or vapours from the chromosphere as they pass through it. Hence the particles which are repelled by light may be either positively or negatively electrified or neutral. Owing to the greater tendency of negative electrons to condense vapours and attach themselves to groups of molecules, the negatively charged particles may be less dense and smaller than those positively charged. It should be noted, however, that isolated molecules or electrons are far too small in diameter to be repelled by light. It is only groups of molecules of at least 500 Å.U. in diameter which can be repelled. Hence these dust particles will travel outwards from the sun with very different velocities. Some will come with great velocity and others with small speed.

In short, we may say that the sun, like a good housemaid, dislikes dust, especially dust of a certain degree of fineness, and pushes it away from it with great force. The moment that this electrified dust enters the earth's magnetic field with high velocity forces will be brought to bear on it tending to separate the negatively and the positively charged particles. If H is the magnetic force of the earth and v the particle's velocity, and e its charge, then the separating force is Hev where H is that component of magnetic force at right angles to the direction of v and the separating force is also at right angles to the plane of H and v.

(To be continued.)

Obituary.

Sir Ernest Shackleton, C.V.O.

THE sudden death of Sir Ernest Shackleton on board the *Quest* at South Georgia on January 5 stopped the career of the most brilliant of Antarctic explorers just on the threshold of the South Polar regions which he was entering for the fifth time with his third expedition. That such a courageous and indomitable explorer should die a natural death after a lifetime of hair-breadth escapes from perils of ice, of starvation, of shipwreck, and of war is a grim stroke of Nature's irony. Great as his loss is to geographical exploration, we cannot but recognise his end as happy, for his life was arrested in the full course of the enthusiastic pursuit of a great and crowning adventure. The sympathy of all who appreciate high-hearted deeds will flow towards his wife, to whose co-operation much of his success was due; towards his shipmates, who have nobly resolved to carry on the voyage; and towards Mr. John Q. Rowett, whose friendship for Shackleton made him undertake the main financial burden of the expedition.

Ernest Henry Shackleton was born at Kilkee, in Ireland, in 1874, removed to London with his father while still a schoolboy, and at an early age insisted on going to sea instead of following his father's profession of medicine. After voyages to South America and other parts of the world, he entered the service of the Union Castle Co., where he was during the stirring days of the Boer War. He had become an officer of the Royal Naval Reserve before the plans of the Antarctic expedition on the *Discovery* fired him with the desire for exploration. His application for a post on the expedition was refused, persisted in, and finally accepted, and he had a strenuous time on board as junior watch-keeping officer. The expedition sailed in August, 1901, and from the outset Shackleton was eager to undertake every piece of voluntary work. He assisted in the chemical and oceanographical observations, assumed the editorship of the *South Polar Times*, and read up the history of polar exploration. When Capt. Scott was making up his party for the great southern journey of 1902–3 he included Shackleton, who thus took part in establishing the "farthest south" of lat. 82° 17′ S., and saw the great range of mountains bordering the Ice Barrier on the west and stretching far to the southward. On the return journey Shackleton broke down from an illness which was probably scurvy, but he struggled on to

the end without giving in, and only last year he refuted with the utmost indignation a published statement that he had been dragged on a sledge by his comrades on that occasion. He was much distressed at the decision that he should return home by the relief ship, and it may well be that this fact was the germ of the determination to return to the Antarctic with an expedition of his own. Shackleton had more than recovered by the time he reached England, and his health never gave way again.

In 1904 he became secretary of the Royal Scottish Geographical Society and took up his residence in Edinburgh after his marriage to Emily, daughter of the late Mr. Charles Dorman. It is scarcely too much to say that the breezy energy of the new secretary electrified the society. Unheard-of innovations were installed, unprecedented expenses undertaken, and a harvest of new members justified every reform. At the general election of 1906 he appeared as the Unionist candidate for Dundee and conducted a vivacious though unsuccessful campaign.

After this, secretarial duties proved too commonplace, and for a time Shackleton found a freer vent for his energies in business life, taking part in one of the great shipbuilding and engineering works on the Clyde. But all the time unseen lines of force were holding his ambition true to the south, and silently but solidly he laid his plans. He bought an old whaler, the *Nimrod*, raised a considerable sum of money under his personal guarantee of repayment if the expedition proved a success, and, profiting by the mistakes of the *Discovery* expedition, he had all his provisions prepared, packed, and stowed under his personal inspection. He had no committee and no orders, but held himself free to carry out his own plans in his own way at his own risk. He decided to base his transport on ponies and motor haulage, methods never used before in polar exploration, and although the motor broke down at an early stage, the ponies brought the expedition to a point on the barrier beyond that reached in the *Discovery* expedition, and but for the loss in a crevasse of the last pony, the South Pole would have been reached. An ascent to the plateau was found by the Beardmore Glacier, and when it was clear that the provisions could not carry the party all the way and back, Shackleton turned in lat. 88° 23′ S. Had he pushed on for another day before turning he would have met the fate which afterwards befell Scott, and, indeed, he very narrowly missed it. On this expedition there were many innovations in food, in lighting, and for the first time it carried a kinematograph into the polar regions.

On his return in 1909 the recognition of the epoch-making advances in methods and results was widespread, if not universal, and the splendid achievement of David and Mawson in reaching first the summit of Mount Erebus and then the Magnetic Pole, together with the biological, meteorological, and geological work of all the parties, gave the expedition, as a whole, high scientific value. Shackleton received a shower of gold medals from the geographical societies of the world and the honour of knighthood. He passed a strenuous year or two lecturing in Europe and America to pay off the debts of the expedition and the expense of the scientific reports.

The attainment of the South Pole by Amundsen and Scott in 1912 turned Shackleton's attention to the project of crossing the Antarctic continent by landing on the shores of the Weddell Sea and marching *via* the Pole to his old quarters on the Ross Sea. Again his word was sufficient security for the advance of funds, and again the plan was his own. The war broke out after his start in the first week of August, 1914, and he at once placed ships, stores, and men at the disposal of the Government for military service. The offer was declined, and the expedition sailed. The Ross Sea party carried out its programme and laid a chain of *depôts* from Macmurdo Strait to the Beardmore Glacier, but the men were imprisoned at their winter quarters by the drifting away of their ship, the *Aurora*. Meanwhile, Shackleton, in the *Endurance*, had carried the exploration of Coats Land farther south than its discoverer, Bruce, or his German follower, Filchner; but just when a landing was almost in sight the ship was caught and drifted northward fast in the ice step by step with the *Aurora* on the other side of the world.

The *Endurance* was crushed and sank, but Shackleton and his party kept up their courage through a dreadful year of inaction. Where reckless daring was the only course everyone knew that he would dare all; but it was a revelation to most of us to find that when safety lay in caution he could command the eager spirits of his companions to patience. When a landing was made on Elephant Island he at once decided to make for South Georgia, 800 miles away, in a little open boat with a few volunteers, and seek help for the others, who remained under the charge of Frank Wild. He made the almost impossible voyage, well knowing that if he survived and the party on Elephant Island perished he would be charged with deserting them and seeking his own safety, and to face this possibility was a greater test of courage than the Southern Ocean itself. He succeeded after three failures in bringing every man who sailed in the *Endurance* back alive to South America in August, 1916.

Hurrying to New Zealand, he found that the authorities who had repaired and equipped the *Aurora* to rescue his Ross Island party refused to allow him to take charge of his own ship to look for his own men; but he felt his responsibility so keenly that with an almost unbelievable magnanimity he accepted the situation and shipped as a common sailor on the relief voyage. Never was a case where failure was so nobly retrieved, and the failure had occurred only because the forces of Nature are stronger than the resources of the most heroic man.

For two years Shackleton served in the army as officer in charge of the supplies for the British force operating in the White Sea and Northern Russia. Then for another feverish spell he threw all his energies into lecturing on his last expedition to enable

him to repay the advances which had been made to him. Once out of debt, he found the call of the ice irresistible. He meditated a dash to the unknown centre of the Beaufort Sea in the Arctic regions, and had gone far to mature his plans when circumstances barred the way, and he resolved on one more Antarctic voyage.

This time the munificence of friends secured him freedom from financial worries. His plan was sound; the Enderby Quadrant which he was to explore was practically unknown; his old comrades rallied to him from the ends of the earth; but the ship was small though stout, and he was forty-seven years old, though a boy at heart. He sailed in the *Quest* in September, 1921, had a grievous buffeting on the voyage to Madeira, a long and trying delay for refitting in the heat of Rio de Janeiro, again a stormy voyage to South Georgia, and then the sudden seizure in the midst of apparent health, and the career of the most Elizabethan of modern explorers had an end as abrupt as the clash of "the blind Fury with the abhorred shears."

Shackleton lived like a mighty rushing wind, and the very strength of his nature made him enemies as well as friends. He resented injustice and slights, but they only spurred him on to show by new achievements how baseless they were. He endeared himself to his friends, and was adored by his ship-mates, who saw in "the Boss" a kindly but unquestionable authority. He loved applause and gloried in the limelight; but he was applauded for feats that no one else was able to accomplish. The labourer is worthy of his hire, and no one has a right to quarrel with a good workman if he likes to take some of his pay in the form of praise and publicity.

Shackleton's most characteristic quality was neither courage nor resolution, both of which he shared with other heroes of exploration. It was his instinctive judgment. Whenever he had to make a decision between two courses of action, no matter how suddenly the necessity arose nor how quickly it had to be met, he invariably did the right thing. Again and again the wrong decision would have meant certain death or irremediable disaster. This power of decision was not an effort of reason, but an apparently instinctive impulse which can perhaps be accounted for by a peculiar balance of perception. Indeed, it is to the balancing of contradictory qualities that much of Shackleton's success was due. His mind was not essentially scientific, though he valued science and made most generous provision for it in his expeditions. He was both impulsive and cautious, yet he was never irresolute. He revelled in poetry and seemed to breathe the air of romance, but at the same time he was a methodical organiser and a keen business man. His imagination was amazingly fertile, and it seems as if in planning an expedition he imaged to himself everything that could possibly happen in any set of circumstances and then set himself to work to provide for each contingency. Whatever may have been its secret, his personality was his greatest power, and it marked him out as a commanding figure. He might well have been a Drake or a Ralegh; in no time and in no conditions could he have been commonplace. The greatness of his loss may be judged by the things he did and the way he did them.

HUGH ROBERT MILL.

SIR WILLIAM CHRISTIE, K.C.B., F.R.S.

WILLIAM HENRY MAHONEY CHRISTIE was the youngest son of Samuel Hunter Christie, professor of mathematics in the Royal Military Academy at Woolwich and secretary of the Royal Society from 1837 to 1854. He was born in 1845, the same year as George Darwin and two years later than David Gill. Educated at King's College School and Trinity College, Cambridge, he was fourth wrangler in 1868, and in the following year was elected to a fellowship of his college. On the recommendation of Airy, Christie was, in the autumn of 1870, appointed chief assistant at the Royal Observatory, Greenwich. At that time the activity of the Observatory was largely concentrated on its traditional duty of the regular observation of sun, moon, planets, and fundamental stars, the stars being regarded as points of reference for the planets, and especially the moon, and serving also for the determination of time. The observations were made with the transit circle erected by Airy in 1850. Christie made a careful study of (1) the most suitable value of the refraction constant at Greenwich, (2) the corrections to be applied for a well-established and persistent difference between the zenith distances of stars when observed by reflection from mercury and when observed directly, and (3) the value of the latitude at Greenwich—data required to deduce the declinations of stars free from systematic errors. In this involved and somewhat indeterminate problem his judgment was correct, as is shown by the smallness of the systematic corrections applicable to the Greenwich catalogues of 1880, 1890, and 1900 to bring them into accord with the mean of other observatories.

The extension of the field of work of the Observatory was pressed on Airy by Warren de la Rue, who advocated continuous observations of sun spots, and by Huggins, who advocated spectroscopic observations of sun and stars. In a letter to Airy in May, 1872, Huggins writes: "I understand Mr. Christie, who is zealous in the matter, to say that you would be agreeable to this course." Government sanction was obtained, and Mr. E. W. Maunder was appointed assistant for photographic and spectroscopic observations. Christie was in sympathy with both these extensions of the activity of the Observatory. The photo-heliographic work was carried through very successfully, and arrangements made with the Solar Physics Committee, and later with the Cape and Kodaikanal Observatories, resulted in a uniform and continuous series of photographs of the sun being taken day by day, which were afterwards measured and discussed at Greenwich with reference to the positions and areas of sun spots.

The spectroscopic observations for velocity in the line of sight were not successful. It was not until the introduction of photography by Vogel that any reliance could be placed on line of sight determina-

tions of velocity, and not until the Mills spectrograph at the Lick Observatory was got into operation in 1895 by Campbell that thoroughly trustworthy results were obtained. But the earlier observers in the field, as in the parallel case of parallax determinations, deserve credit for attacking an important problem, though they did not succeed in overcoming the great difficulties which it presented.

On the retirement of Airy, in 1881, Christie was appointed Astronomer Royal. His tenure of office is notable for the large additions he made to the equipment of the Observatory and to the introduction of stellar photography. The first extension of the buildings was an additional computing room, and with it a pier and dome, which served later for the astrographic equatorial. In 1885 he represented to the Admiralty the desirability of increasing the optical means of the Observatory, and received its assent to the purchase of an object-glass of 28-in. aperture and 28-ft. focal length. In co-operation with Stokes an object-glass was proposed which might be used for visual or photographic observations. This telescope, constructed by Sir Howard Grubb, was completed in 1893 and installed on the equatorial mounting which until then had carried the Merz 12¾-in. telescope. The drum-shaped dome covering the Merz refractor was worn out, and was replaced by an Oriental-looking dome designed by Christie to contain the longer telescope. This telescope was for many years in charge of Mr. Lewis, and has been utilised for a valuable series of observations of double stars.

The provision of the photographic refractor of 13 in. with a 10-in. guiding telescope, to enable Greenwich to take part in the photographic mapping of the heavens, was sanctioned in 1888. The instrument, constructed by Sir Howard Grubb, was mounted in the 18-ft. dome over the computing rooms in 1890. The Greenwich section of the astrographic chart and catalogue and the observations of Eros for solar parallax were made with this telescope. Christie took a share in the deliberations and arrangements for this international undertaking. He designed a micrometer for use at Greenwich which facilitated the comparison of neighbouring plates. He was also the discoverer of a very useful empirical formula connecting the magnitude of stars with the diameter of their photographic images.

The largest addition to the Observatory was commenced in 1890, but not completed until 1898. It is a cruciform building, with office rooms on the ground floor, libraries and workshop in the basement, rooms for preserving records and photographs on the upper floor. The central octagon is used as a store room, and is surmounted by a 36-ft. dome originally built to cover Lassell's 2-ft. mirror presented to the Observatory by the Misses Lassell. Before the building was completed Sir Henry Thompson generously offered to provide a 26-in. photographic refractor and a 30-in. reflector, both on the same equatorial mounting. The equatorial and the refractor were constructed by Sir Howard Grubb and the mirror by Dr. Common. The refractor was used in observations of Eros, observations of Neptune's satellites, and for various other purposes, while the reflector was used in photography of nebulæ, observations of small planets, comets, faint satellites, etc., and was instrumental in the discovery of the eighth satellite of Jupiter.

About the same time Christie designed a new altazimuth. The instrument is essentially a transit circle which can be mounted in any azimuth. It replaced Airy's altazimuth, which did not give sufficient accuracy. The new instrument usefully supplements the observations of the moon made with the transit circle.

These various extensions to the Observatory buildings cramped the space for meteorological observations, and the iron in the domes affected the magnets, which were housed in a wooden building a few yards to the north of the new observatory. A plot of ground in Greenwich Park was lent to the Admiralty by the Office of Works, where a magnetic pavilion was erected for taking absolute magnetic observations.

Christie took a good deal of interest in the observation of total eclipses. He went to Japan in 1896, to India in 1898, to Portugal in 1900, and Tunis in 1905. With the equipment arranged by him in 1896 an excellent series of large-scale photographs of the corona were taken at the eclipses of 1898, 1900, 1901, 1905, and 1914.

Christie retired from his office on his sixty-fifth birthday, October 10, 1910, with the good wishes of his staff. He maintained his interest in the Observatory, and came regularly to the annual visitation. He was also frequently at the meetings of the Royal Astronomical Society and the Royal Society, serving on the council of the Royal Society six years and on that of the Royal Astronomical Society forty-one years, being president in the years 1888–1890. Several foreign academies also accorded him honours. He received the distinction of C.B. on the occasion of Queen Victoria's Diamond Jubilee and was promoted K.C.B. in 1904.

He married in 1881 Violette Mary, daughter of Sir Alfred Hickman, of Wolverhampton. Mrs. Christie died in 1888, leaving two sons, one of whom died in childhood. His elder son, Mr. Harold Christie, lived at the Observatory until his father retired, when they went to live first at Woldingham and afterwards at Downe. Sir William was of a courteous and hospitable disposition, and would always invite some members of his staff to meet a foreign astronomer who might be visiting the Observatory. He thoroughly enjoyed astronomical conferences and eclipse expeditions for the opportunities they afforded of meeting astronomical colleagues. He acquired in these expeditions a love of sea voyages, and after his retirement made several trips abroad in the winter. In the early part of 1921 he went to Jamaica, and paid a visit to Mr. and Mrs. Pickering at the observatory of Mandeville. This year he started for Mogador a few days after meeting many of his friends at the Royal Astronomical Society Club. He was then apparently in fair health, but died on January 22, before the ship reached Gibraltar.

F. W. DYSON.

Dr. Emile Cartailhac.

We regret to record the death of Dr. Emile Cartailhac on November 25 at Geneva, where he had just completed a course of lectures delivered at the invitation of the University. Emile Cartailhac was born at Camarès in 1844, and for more than fifty years had been one of the dominant figures in the study of prehistoric archæology in France. His work in archæology began when the discoveries of Boucher de Perthes were still the subject of controversy, and he threw himself with characteristic ardour into the discussion. He settled early at Toulouse, and founded there in 1866 a museum of human palæontology. His success as a lecturer was immediate, and eventually led to his appointment as professor of prehistoric archæology, the only appointment of the kind in France. From 1869 onward he edited the well-known publication, "Matériaux pour servir à l'Histoire primitive et naturelle de l'Homme," with conspicuous ability; but his greatest contribution to prehistoric archæology was his synthetic study of the prehistory of France which appeared in 1889 under the title, "La France préhistorique d'après les sépultures et les monuments." This book, the first of its kind, has gone through numerous editions. Of his other writings, which were numerous, the most important were "Ages préhistoriques de l'Espagne et du Portugal," the volume dealing with the rock paintings of Altamira in the series published under the auspices of the Prince of Monaco, written in conjunction with the Abbé Breuil, and the archæological section of "Les Grottes de Grimaldi."

Mr. Mansel Longworth-Dames, whose death in his seventy-second year is reported, entered the Indian Civil Service in 1868. He served in the Punjab for twenty-eight years, with an interlude in 1879, when he was on duty with the troops in the second Afghan war. While he was stationed in the trans-Indus districts he acquired a good knowledge of the Baluch tribes and of their language; he published a Baluchi grammar and reading-book, which were for many years used by students; an account of the Baluch race, issued by the Royal Asiatic Society; and "The Popular Poetry of the Baluchis," published by the Folklore Society. He made a large collection of Buddhist art, which passed into the hands of the Berlin Museum, and he helped to arrange the Buddhist rooms of the British Museum. He was an active member of the Royal Asiatic Society, of which he was vice-president. He knew Arabic, Persian, and Portuguese well, and this knowledge he utilised in his new translation, with copious annotations, of "The Book of Duarte Barbosa," published last year by the Hakluyt Society. His death leaves a gap in the small circle of oriental scholars.

We regret to report the death of Mr. C. F. T. Hadrill, clerk in the General Library of the British Museum (Natural History). Seized on January 12 with influenza while on his way home from the Museum, he succumbed to its effects within four days, on the evening of January 16. Mr. Hadrill first took service with the Trustees in the Copyright Office at the British Museum, Bloomsbury, in 1888. Thence he was transferred to the General Library at the South Kensington division of the Museum in 1895. Save for the period of his war service (1915 to 1919), he held his position continuously up to the day of his death. Thoroughly interested in his work, in which he took great pride, he was intimately acquainted with the books under his charge, as all who came into contact with him, whether Museum officials, or students, or casual visitors, soon realised; and his services, always most willingly, obligingly, and efficiently rendered, were consequently in perpetual demand. His loss will be felt as a personal one by a large circle of scientific workers, including those connected with the "Zoological Record," for which he was one of the researchers.

Notes.

The Bakerian lecture of the Royal Society will be delivered on March 9 by Prof. T. R. Merton and Mr. S. Barratt on "The Spectrum of Hydrogen."

The fifth Silvanus Thompson memorial lecture of the Röntgen Society will be delivered by Sir Oliver Lodge at the Institution of Electrical Engineers on Tuesday, March 21.

At a meeting of various sections of the welding industry held on January 26 it was resolved that a new society, to be known as the Institution of Welding Engineers, be formed. The society will embrace all systems of welding, and anyone who is interested in welding and allied industries will be eligible for membership. The hon. secretary (*pro tem.*) is Mr. C. Raggett, and the temporary home of the new institution is at 30 Red Lion Square, London, W.C.1.

Information has reached us from Mr. D. H. Cain, 13 Duke Street, St. James's, S.W.1, that an English company, known as Radium Ore Mines, Ltd., is to re-open the Tolgarrick radium mine situated near Truro. According to this announcement, the mine was abandoned at the outbreak of the war, but is already installed with all the plant necessary for immediate resumption of work. Two rich lodes of uranium ore are to be worked, and the intention is to treat the ore on the spot. The development of radium spas in this connection is also foreshadowed.

Two noteworthy prizes for the discovery of a cure for cancer have recently been announced, namely, one by Lord Atholstan of 100,000 dollars, and the other by Sir William Veno of 10,000*l*. Both prizes are limited to students and graduates of recognised universities, and they will be awarded to the first investigator who within the next five years succeeds in discovering a non-surgical effective cure for cancer. The awards will be made on the decision of the Royal Colleges of Physicians and Surgeons in London.

At the monthly meeting of the Zoological Society of London, held on January 18, the secretary reported that seventy-nine additions had been made to the society's menagerie during the month—thirty by presentation, thirty-nine deposited, and ten by purchase. The most noteworthy addition to the collections is a pair of lions from India, presented by H.M. the King. The number of visitors to the gardens during 1921 was 1,386,745, and the receipts for admission amounted to 46,509*l*. Four hundred and seven new fellows were elected to the society during the year, and while this number is 123 fewer than in the previous year, it is 95 above the average for the last ten years. These figures are eloquent of the popularity of this institution.

A movement has been set on foot to erect a fitting memorial to the great sanitarian, William Crawford Gorgas, through whose labours it became possible to complete the construction of the Panama Canal. Inaugurated by Dr. Belisario Porras, the President of the Republic of Panama, the scheme aims at the erection of a hospital and laboratory for tropical and preventive medicine. The Panama Government has provided a site, a building, and modern equipment valued at half a million dollars, as well as the use of the two-million-dollar Santo Tomas Hospital, which is just being completed. It is hoped to increase the initial sum available by another four and a half million dollars by means of contributions from the public and the Governments which have benefited from the work of Gorgas. A provisional board of directors for the United States has been appointed. The laboratories to be built will resemble the Pan-American buildings in Washington, while Dr. R. P. Strong, of the Harvard School of Tropical Medicine, is to be the scientific director of the memorial.

Shortly after the retirement of Prof. P. F. Frankland from the Mason chair of physics in the University of Birmingham a fund was opened with the object of providing some permanent memorial of his work in the University. The money subscribed was devoted in the first place to a portrait of Prof. Frankland (painted by Mr. Bernard Munns), which now hangs in the great hall of the University at Edgbaston. The balance of the fund has been applied to the institution of a Frankland medal, which, together with a prize of books, is to be presented annually to the best student in practical chemistry. The medal is of bronze, bearing on the obverse a profile portrait of Prof. Frankland, and on the reverse the arms of the University. A handsome book-plate has also been designed to be placed in the prize-books. The name of this distinguished chemist will thus be kept green in the memory of future generations of students, and the prize will doubtless act as a stimulus to the attainment of excellence in the practical study of chemistry, on the importance of which Prof. Frankland so wisely insisted.

The Gypsy Lore Society, founded in 1888 by Mr. David MacRitchie to promote the study of the language, history, ethnology, and folk-lore of the gypsy race, continued its useful career until its publications were suspended in 1892. After fifteen years it was revived under the direction of Mr. R. A. Scott Macfie, but its work again ceased owing to the war in 1914. We are glad to learn that the society has now been revived again under the presidency of Mr. W. Ferguson, with Mr. T. W. Thompson as honorary secretary. The address of the honorary treasurer, to whom the subscription of 1*l*. per annum is payable, is 7 Macdonald Road, Friern Barnet, London, N.11. The society in its new form has received the support of several eminent scholars interested in the subject, and many valuable contributions have been promised. The study of the gypsies is to be commended from many points of view and we trust that the society will receive generous support and meet with the success which it deserves.

In 1821 some residents of New South Wales of a scientific turn of mind founded the Philosophical Society of Australasia, the first scientific society to be formed in Australia. The society did not continue its meetings for long, and while other societies devoted to agriculture, horticulture, botany, etc., were formed, it was not until 1850 that a society for general science known as the Australian Philosophical Society, with Sir Thomas Brisbane as president, came again into existence. Only two members of the original society were also members of the 1850 society, namely, Alexander Berry and Dr. H. G. Douglass, the latter of whom was honorary secretary of both societies. In 1855 the name was changed to the Philosophical Society of New South Wales, and in 1866 this name gave place to that of the Royal Society of New South Wales, which it still bears. To commemorate the centenary of the foundation of the parent society, members of the Royal Society of New South Wales visited Kurnell on December 10 last, where the president and members of the original society had erected a brass tablet in memory of the landing of "James Cook and Joseph Banks."

Influenza in London had very appreciably decreased according to the deaths given in the Registrar-General's return for the week ending January 21; the decrease compared with the preceding week was 108. In the ninety-six great towns of England and Wales the deaths had increased in the corresponding period by 164, but there seems a good prospect that the improvement shown in London will extend to other parts of England. Of the total deaths from influenza in London during the week 56 per cent. occurred between the ages of forty-five and seventy-five. In London there have been with the present attack thirty-one epidemics since 1890, considering a well-established 20 or more deaths per week as epidemic. The only years without an epidemic are 1896 and 1901, and of the thirty epidemics preceding the present, twenty-seven have occurred in March, twenty-four in February, eighteen in April, and seventeen in January. Not one has been existent in September, only one in August, two in July and October, and three in June. The complaint is essentially epidemic in winter and spring, but there seems little

indication of it being helped or hindered by spells of heat or cold.

English engineers are glad that it is highly probable that the contract for the electrification of the South African Railway between Pietermaritzburg and Glencoe will be given to the Metropolitan-Vickers Co., of Manchester. In the early days of the electrical industry in South Africa German competition was severely felt, but much of the foreign-made plant then purchased has given great trouble to the users, due not only to faulty design, but also to the fact that it got much too hot at full load. English machines were found to be more desirable. The contract will involve the construction of seventy locomotives. The line carries very heavy mineral traffic on its way to the coast in Natal and goes through a hilly district. It is, therefore, very suitable for electric traction, as regenerative braking can be used on the descending grades. In addition to pumping back into the line most of the potential energy lost, it obviates all the wear and tear on wheels and brake-shoes inevitable with steam traction. Each of the locomotives will be equipped with four large electric motors, and the construction of these and the necessary control gear will, unless the unforeseen happens, provide employment for many workpeople in Sheffield and Manchester.

The thirteenth meeting of the International Geological Congress is to be held in Brussels on August 10–19. Excursions to places of geological interest in Belgium will be held before the congress, on August 1–9, and afterwards from August 21–September 3. An interesting programme of geological discussions on subjects including tectonics, the geology of the Carboniferous system and of petroleum, and the geology of Africa—a subject to which Belgian geologists have contributed greatly. The committee of organisation has decided not to admit ". . . nationals of those countries lately at war, in defiance of Treaty obligations, with Belgium"—a phrase which only an international lawyer could confidently interpret. It might be intended to exclude Germans only, but might admit of considerable extension. The admission of Germans and Austrians to the social functions of the congress might be reasonably regarded as premature, but their complete exclusion from an international scientific congress will be regretted by many British geologists. The president of the organising committee, who will naturally be president of the congress, is M. J. Lebacqz, Director-General of Mines, and president of the Geological Council in Belgium. The secretary is M. Renier, the head of the Geological Survey of Belgium. There will be five excursions before the congress to examine respectively the central and eastern districts, the Tertiary beds, the Devonian, and building materials. There will also be ten local excursions, most of which are for a single day, during the congress. Five excursions after the congress will be devoted to the study of the Cretaceous and Tertiary rocks near Mons, the metamorphic rocks at Bastogne, the Palæozoic tectonics, the Carboniferous limestones, and the Westphalian. These excursions vary from four to twelve days.

The Secretary of State for Air, Capt. Guest, received a deputation from the council of the Royal Aeronautical Society on January 17 and heard views for safeguarding the applied scientific research of the Air Ministry. Attention was directed to the danger of dealing exclusively with the needs of the moment, particularly by routine methods, and to the fact that present and future economy called for systematic inquiry on scientific principles. The high insurance rates required to cover aviation risks and the loss of the airship R38 are instances which will occur to readers of Nature as matters needing more than passing attention. The deputation consisted of Col. M. O'Gorman (chairman), Prof. L. Bairstow, Sir Mackenzie Chalmers, Prof. B. M. Jones, and Lt.-Col. A. Ogilvie, and represented the council of the Royal Aeronautical Society, except that Service members felt that their appointments debarred them from expressing an opinion. A marked distinction was made between "applied scientific research" and "*ad hoc* experiments," and it was stated that experience showed that the latter take precedence and tend to the extinction of research on the ground of urgency when both are under a common direction. The cessation of airship research both on the full scale and in the laboratory and the proposal to close the Aerodynamics Department of the National Physical Laboratory (happily not being fully pressed) indicate how serious has been the position in the past year. The deputation suggested that the remedy lay in the appointment of a scientifically trained head of a department specially devoted to applied scientific research. As applied to a new science the difficulties are great, but it is understood that the proposals are receiving the serious and sympathetic consideration of the Secretary of State for Air.

The report of the "Wireless" Telegraphy Commission which has just been issued is of value, as it represents the reasoned and deliberate judgment of three well-known experts. In his preface Dr. Eccles comments on the "severely technical" nature of the report, but as the terms of reference definitely ask for advice on the preparation of specifications for machinery and apparatus this was unavoidable. The Commission is to be congratulated on the thoroughness with which it has done its work. As in all engineering projects, however, unless the scheme is begun at once further discoveries may make it advisable to alter appreciably the detailed specifications. It recommends that a radio-chain be established, none of the steps being greater than about 2000 miles. The radiotelegraphic energy is to be generated by thermionic valves. The first step is to be from Leafield to Cairo, which the Post Office will shortly operate by means of Poulsen arcs. Then valve stations will be erected at Poona, Singapore, Hong Kong, and in Australia at either Port Darwin or Perth. Valve stations would also connect England and Canada. The stations are to be capable of delivering at least 120 kilowatts to the antenna. They will be larger, therefore, than the Carnarvon station of the Marconi Company. It has been found that there is a considerable loss of

energy due to the induced currents in the earth under the antennæ. The Commission therefore advises that efficient earth-screens made of grids of copper wire be used at all the chain stations. It is suggested that the Marconi Company be invited to tender for earth-screens, antenna tuning coils, and thermionic-valve sets. It also suggests that if their tender be not acceptable, suitable plant could be designed by the Commission after the conclusion of the work now being undertaken at Horsea.

THE last annual report from the Field Museum of Natural History at Chicago deals with the highly successful removal of the collections from the building in Jackson Park to a new building in Grant Park. The Section of Plant Reproduction continued to turn out those beautiful models of vegetable structure on which we have commented in previous years. In addition to several fruits and flowers, the reproductions include the green algæ, Œdogonium and Ulothrix, enlarged tip of a frond of the alga, *Bryopsis plumosa*, a cotton plant, and a cycad, *Zamia floridana*. Another reproduction illustrated, but not otherwise mentioned, in this report is a restoration of the New Zealand moa, 13 ft. high. We do not know which species of Dinornis this professes to represent, but it seems to have an abnormal number of cervical vertebræ, a mammalian back, and pantomime legs.

IN "La Cité des Termites" Dr. J. Feytaud gives a very interesting account of the social habits of *Leucotermes lucifugus*, Rossi. The author has had excellent opportunities to study this species of white ant (one of the two species of the family found in Europe) at first hand in the south-west of France, and he has made good use of them. The brochure contains one of the most complete studies of the life and habits of the termites that we have. Much of the information has appeared in scientific journals, but now that the author has brought his studies together into one volume the intricate and elaborate social life that exists amongst termites should become more widely known. A chapter is devoted to the ravages and means of destruction of termites.

SOME interesting anthropological data relating to the Pitcairn Islanders, the descendants of the mutineers of the *Bounty*, are contained in an appendix by Dr. D. Colquhoun, of Dunedin, New Zealand, to a report on a visit paid in June last to Pitcairn Island by Sir Cecil Rodwell, High Commissioner of the Western Pacific (Colonial Reports—Miscellaneous: No. 93). The present inhabitants, who number 174, are the descendants of forty of the islanders who, in 1859, returned to Pitcairn from Norfolk Island, whither the whole population of 190 had migrated in 1856. Dr. Colquhoun describes the islanders as lighter in complexion than pure Maoris, and says many would pass for southern Europeans. The hair is generally dark and straight, although one individual had the frizzy hair, dark skin, and thick lips of a Melanesian type, and two children had fair hair and blue-grey eyes. Generally the eyes are dark brown, rarely bluish-grey. All the islanders are dolichocephalic. No stigmata of the degeneration through in-breeding, which was anticipated from the evidence afforded by Admiral Palliser's visit to the island in 1898, were observed, and the island is singularly free from disease. Copies of the report may be obtained from H.M. Stationery Office, Imperial House, Kingsway, W.C., price 10*d*.

RÉSEAU MONDIALE, 1914, has recently been published by the Meteorological Office of the Air Ministry. The preface to the work is written by Sir Napier Shaw. The present volume completes five years of the publication, 1910 to 1914, which will afford some idea of the value of the compilation of meteorological data for the whole globe which it has been the ambition of meteorologists to achieve for a long time past. Data for 1914 were not obtainable until some time after the war, and information for many of the Siberian stations is still lacking. The number of stations recorded for the present volume is 392. Two stations are chosen for each ten-degree square, and the results are given for each month and for the year. For barometric pressure the mean is shown with the difference from the normal. For temperature the mean maximum and mean minimum values are tabulated with the mean of the maximum and minimum and the difference from the normal, together with the absolute maximum and absolute minimum temperatures experienced. For rainfall the total precipitation is given and the difference from the normal.

THE report of a general discussion on the physics and chemistry of colloids, held jointly by the Faraday Society and the Physical Society of London, has been issued by the Stationery Office at the price of 2*s*. 6*d*. It includes nearly thirty formal papers on colloids, in addition to the discussions arising therefrom. Special attention may be directed to the brilliantly lucid "Survey of the Physics and Chemistry of Colloids," by Prof. Svedberg, of Upsala, with which the proceedings were opened. The essential outlines have been drawn with a clearness and firmness of touch that has never before been equalled, whilst the bibliography at the end of the paper shows where the details required to complete the picture may be found.

THE demand for very penetrating X-rays for purposes of medical therapy has led to the construction of high-tension apparatus capable of giving a continuous output for several hours of current at an alternative spark-gap up to about 18 in. This has caused considerable modifications in the design of both induction coils and interrupterless transformers. A circular on "Deep Therapy Apparatus, Section 2b," issued by Messrs. Newton and Wright, Ltd., gives a description of an induction coil designed for this type of work. The coil really consists of two symmetrical coils mounted side by side, the whole being immersed in oil; this latter avoids breakdowns due to insulation troubles produced by the high-tension discharges in the air in the interior of the coil. A useful feature of the double-

coil design is that it allows the milli-ampere meter to be inserted at the mid-point, which is at zero potential, and hence the instrument can be brought to an ordinary low-tension switchboard.

AN account of the discussion on the future of geometrical optics which took place at the Cambridge meeting of the Optical Society in May last is given in part 5 of the Transactions of the society for the present session. On the whole, the representatives of the manufacturers were in favour of retaining the step-by-step trigonometrical method of tracing rays through the system under design in order to get rid of aberrations rather than changing to the analytical methods, which give the aberrations of the first order in terms of a certain quartic in the magnification and those of the second order in terms of

$$M(1+AM)/(1+BM),$$

where A and B are constants and M is the square of the inclination of the ray to the axis. It was, however, suggested that some attempt should be made by mathematicians to reduce the complexity of the formulæ involved by bringing the subject into line with the wave theory. It was pointed out that the British optical trade must in the next four or five years improve its optical designs if it is to be able in the future to sell its products against the better designed articles offered by manufacturers of other countries.

A LIST of American research chemicals has been issued as No. 23 of the Reprint and Circular Series of the National Research Council, Washington. The list includes biological stains and indicators, and includes a very large number of fine chemicals. The number is larger than that in the corresponding list of British research chemicals, issued by the Association of British Chemical Manufacturers, but the latter is incomplete, and although not dated, was issued some time before the American list. The American list also includes many very simple derivatives, such as acetyl and benzoyl compounds, which swells its bulk. One noticeable feature of the American list is that it includes a large number of rarer inorganic chemicals likely to be required for research purposes, whilst the British list is largely made up of organic chemicals. It is desirable that a new and more complete edition of the latter should be issued as soon as possible, and that requirements in inorganic, as well as organic, chemicals should be kept in mind.

THE provision of a works laboratory is now recognised as an essential part of the organisation of any large engineering firm. The equipment will, of course, depend upon the kind of work carried out by the firm. The laboratory at the Bedford works of Messrs. W. H. Allen and Sons, Ltd., forms the subject of an illustrated article in *Engineering* for January 13, and its equipment may be taken as an excellent example of what is required by a firm manufacturing a wide range of high-grade mechanical engineering products. There is a main mechanical testing-room, a chemical laboratory with balance-room and stores, a recalescence room, a photomicrographic room, dark room, and office. The mechanical testing equipment includes a Brinell hardness machine, a Sankey autographic bending machine, machines for repeated impact testing of the Eden-Foster and Stanton types, an Izod impact machine, a 30-ton Buckton machine with a Ewing extensometer, and a Shore hardness testing machine. The same room contains a number of machine tools for the preparation of specimens. The chemical laboratory has also a very complete equipment; the recalescence furnace is a modification of the one in use in the National Physical Laboratory. It is perhaps unnecessary to add that this laboratory has exercised a very effective control over the quality of the firm's products.

AN introductory address to his lectures at University College on waterways, harbours, and docks was delivered by Dr. Brysson Cunningham on January 24. The great value of the ocean as an international waterway and the facilities it affords for traffic, with far fewer difficulties than in the case of land routes, were emphasised. Before the war railway construction in England had cost something more than 50,000*l*. per mile, including expenses of promotion, while in the United States the cost averaged only about one-fifth of this sum; the outlay for track formation proper was about 5000*l*. or 6000*l*. per mile. In both cases there is, in addition, the expense of maintenance, whereas in a waterway on the high seas there is neither cost of construction nor of upkeep. This is true, though in a lesser degree, of the rivers and inland waterways. Dr. Cunningham also discussed ports, pointing out that few modern ports have kept pace with the requirements of the naval architect in regard to ship design. Rational developments in shipbuilding are impeded by lack of depth of water at the principal ports and in the Suez Canal. The following table shows the actual rate of expansion in the dimensions of vessels in the mercantile marine during the past forty years:—

Average dimensions of the twenty largest steamships in each of the years mentioned.

	1881. Feet.	1891. Feet.	1901. Feet.	1911. Feet.	1921. Feet.
Length.. ..	460	507·0	599	703·5	735·0
Breadth ..	45	54·5	65	73·6	82·5
Depth	30	31·0	39	47·7	51·0
Loaded draught	24	27·0	32	32·5	34·0
Tonnage ..	4,900	6,980	14,150	21,600	31,550

Sir John Biles has claimed that it would be economical to construct vessels up to 1000 ft. in length provided it were possible to give them the appropriate draught of 57 ft., but there are very few ports in the world which could receive a vessel of this draught. Forty feet is the extreme limit of draught which is available at the present day for sea-going vessels.

IN the general article on "Agriculture at the British Association" in NATURE of January 5, p. 25, it was stated that "Mr. M. M. Monie gave an account of a photographic survey of soils . . . the method he proposes, while of limited use by itself, should have a useful place in soil-survey work." Mr. Monie writes to say that his remarks were "that a photographic

record of topography, soil profiles, and soil types in the field was a most useful section of my soil survey, forming about 10 per cent. of the work." As an illustration of the value of the method, he showed a telephotograph of an area covered by mounds of fluvio-glacial sands and gravels. Mr. Monie also states that the field methods he has worked out for the West of Scotland can easily be applied to give useful results over most areas.

The reviewer of the translation of Prof. le Blanc's "Text-book of Electrochemistry" in last week's Nature, p. 101, remarked that though the title-page bore the date 1920, he could find no references later than 1907. It has been pointed out to us, however, that the translation, as stated on the title-page, is of the fourth German edition, and that the author's preface to this edition, dated 1906, is printed in the volume. The translators state in their preface that the work is a translation of this edition, and at the back of the title-page are printed the words "Published March, 1907." It was not suggested by the publishers, therefore, that the work was anything more than the fourth edition; the date on the title-page was merely that of the current reprint.

Referring to the notice in Nature of January 12, p. 59, of the new petrological microscope manufactured by Messrs. R. and J. Beck, the firm wishes it to be known that the left-hand slow-motion milled head is provided with graduations each of which represents 0·01 of a millimetre.

Messrs. Bowes and Bowes, Cambridge, have just issued a MS. list of recent books dealing with mathematics on sale by them, and another of works in the German language. Messrs. H. K. Lewis and Co., Ltd., 136 Gower Street, W.C.1, have sent to us a list of the new books and new editions added to their Medical and Scientific Library during October–December. These lists and that of "Recent Scientific and Technical Books" issued with Nature of January 26 should make it possible for readers to keep abreast of current scientific literature.

Messrs. Chapman and Hall, Ltd., are about to publish a book by Dr. G. W. C. Kaye entitled "Industrial Applications of X-rays," which aims at presenting in language not too technical the various uses to which the rays can be usefully applied in commercial undertakings. Another book in the announcements list of the same publishers is "Mechanical Testing," by R. G. Batson and J. H. Hyde, 2 vols. Vol. 1, which will deal with the testing of materials, is expected to be published in February, and vol. 2, treating of the testing of apparatus, either in May or June.

Our Astronomical Column.

The Total Solar Eclipse of next September.—The Greenwich Expedition which is being sent to Christmas Island for this eclipse, consisting of Messrs. H. Spencer Jones and P. J. Melotte (the former being accompanied by his wife), sailed from Liverpool on January 28 in the s.s. *Mentor* (Blue Funnel Line). It is hoped by May to have the instruments ready for observation; the apparatus taken weighed 4 tons, including the 13-in. astrographic equatorial, which will be used for stellar photometry, to connect the magnitude scales of the northern and southern hemispheres, in addition to the eclipse programme, which is simply a repetition of the testing of the Einstein light-shift. The stars are fainter than those of the 1919 eclipse, but the replacement of the cœlostat by an equatorial should bring a great gain in definition.

The *Times* of January 27 makes the welcome announcement that the Commonwealth Government will put a warship at the disposal of the parties visiting Wollal, Western Australia; these include a large party from the Lick Observatory, also parties from Toronto and New Zealand and some Australian astronomers. This will be of great assistance to the parties, but will not remove all their difficulties, as there is no harbour in the neighbourhood, and ships have to anchor some miles out, and land passengers and goods by boats through a surf that is often heavy.

Mr. J. Evershed, director of Kodaikanal Observatory, hopes to observe the eclipse from the Maldive Islands.

The Pleiades.—Lick Obs. Bull. No. 333 contains an important study of this cluster by Mr. Robert Trumpler. The stars belonging to it are distinguished from the background stars by their proper motion; Boss's value for the bright stars is 5·4″ per century in position angle 157·9°. A list is given of 246 stars, of magnitudes between 2·8 and 15·2, that are concluded to be members of the cluster; this conclusion is supported in the case of the fainter stars by the fact that the average motion of stars of these magnitudes is much smaller. The conclusion is strengthened by an examination of spectral types; these are found directly for the stars brighter than magnitude 11, and inferred from the colour-index for the fainter ones. On plotting spectral class against magnitude a smooth curve is found, which descends less steeply in the middle portion than at the ends; it is interesting to note that a practically identical curve was reached at Greenwich by Messrs. Davidson and Martin on plotting effective wave-length against spectral type for stars in the Greenwich astrographic zone.

Inferring the absolute magnitudes for each spectral type from stars of known parallax, the parallax 0·008″ is found for the Pleiades. The hypothetical parallax deduced from the binaries in the cluster is 0·010″, while Hertzsprung and Hartmann found 0·014″ from the parallactic motion of the group. It is inferred that the round value of 100 parsecs, or 320 light-years, is close to the true distance. One very interesting fact is that the red and yellow stars in the cluster are dwarfs, the only giants being those of type B and perhaps a few of type A. It will be remembered that on Russell's theory the B type is the latest of the giant stages, so that the cluster would seem to be in its old age. Examination of the binary stars supports Aitken's conclusion that stars of considerable mass are more likely to divide. Another point noted is the deficiency of stars of type F, suggesting that this may be a short-lived stage. The average star density of the whole group is about ten times that in the sun's neighbourhood. That in the centre of the group is still greater. Correcting for the sun's motion, the speed of the group is 9 km./sec.

Chemistry at the British Association.

THE attendance at Section B during the Edinburgh meeting of the British Association was exceptionally large, and was well maintained throughout, so that, although the meeting-place of the section was the commodious chemistry lecture-room of the University, it was sometimes impossible to find accommodation for all those who wished to hear the discussions. The joint meetings with other sections were very popular, and the practice adopted by the section in recent years of having only a small number of papers at each session led to the interest in the proceedings being well maintained owing to the full discussion of important papers.

The programme contained a number of contributions to the subject of chemistry in its bearing on the problems of animal and vegetable life. The joint discussion with the Section of Physiology on oxidations in living tissues has already been reported (Nature, November 10, 1921, p. 353). The president's address on "The Laboratory of the Living Organism" (Nature, October 20, 1921, p. 243) was one of the most successful features of the meeting. Dr. Forster omitted the more technical portions of his printed address, and delivered an exceptionally lucid lecture which must have made clear to many students of chemistry who had not previously studied recent work in biochemistry both the importance of the subject and the fascinating character of the reactions which take place at atmospheric temperatures and without the presence of energetic condensing agents in the living organism. The paper by Prof. Robinson, which followed on the presidential address, elaborated one aspect of the same subject, the author indicating the reactions by means of which flavones, anthocyans, and other compounds which occur naturally as plant pigments may be derived from carbohydrates by condensations which are capable of occurring at the atmospheric temperature.

Profs. Baly and Heilbron and Mr. Barker dealt with the synthesis of formaldehyde and carbohydrates from carbon dioxide and water under the influence of light. These reactions are brought about by light of very short wave-length, but in the presence of certain coloured substances, which act as photo-catalysts, they can take place in light of a lower frequency. Chlorophyll, on account of its optical properties, is an ideal photo-catalyst for both stages of the carbohydrate synthesis. Dr. E. J. Russell pointed out that although magnesium is an essential constituent of chlorophyll, the addition of magnesium salts to the soil does not increase the amount of photo-synthesis in plants, as does the addition of that of potassium salts. He also remarked that the first product of carbohydrate synthesis in the plant is cane-sugar, which is then hydrolysed. The formaldehyde hypothesis, proposed fifty years ago by von Baeyer, is thus still a matter of controversy. A paper by Prof. Jaeger, of Groningen, had to be taken as read on account of the time occupied by the preceding discussions. In this the author showed that the decomposition of simple organic acids and their salts in solution by ultra-violet light was in a high degree dependent on the presence of catalysts, the results thus having a bearing on the question of photo-synthesis.

Another group of papers dealt with physical chemistry. The discussion on the structure of molecules, held jointly with Section A, was highly successful, and has already been reported (Nature, October 13, 1921, p. 218). Theories of atomic structure, which have hitherto been the special concern of the physicist, are now invoked to explain chemical phenomena, especially those connected with valency; hence the new interest taken by chemists in the subject. Three papers on surface tension were also communicated to the section. Prof. Jaeger described the experimental methods by which he has been able to measure the surface tension of liquids between the temperatures of $-80°$ and $+1625°$ C. The method consists in determining the pressure needed to cause a gas bubble to burst when emerging from a platinum capillary immersed to a known depth in the liquid. The results obtained from molten salts indicate that if Eötvös's relations be assumed to hold, these liquids must be highly associated, but that the validity of the assumption is doubtful. The method is not applicable to metals, as it is necessary that the liquid should wet the platinum. Mr. Cosmo Johns described his observations on the surface of freely flowing liquid steel. The optical properties of such a surface indicate that it is free from oxide, and the author has previously explained this fact as being due to an atmosphere of iron vapour. Evidence for such an atmosphere was now given, the particles collected from the atmosphere near to the outlet of the furnace being relatively richer in manganese (the more volatile metal). The behaviour of these fine particles under the influence of gravity and of a magnetic field was also described. Prof. Desch gave an account of measurements of foam cells in soap and other foams. The most frequently occurring figure proved to be the pentagonal dodecahedron, slightly distorted. An examination of the crystal grains of several metals proved that these grains had the form of foam cells, graphs showing the frequency of occurrence of similar faces coinciding completely, from which the conclusion was drawn that the grain boundaries are determined by surface tension.

A question of national interest was raised by the paper on the modern dye industry contributed by Prof. H. E. Fierz, of Zürich. The main argument of the paper was that the capacity for production of dyes now largely exceeded the demand, and that it was impossible for the dye industry to remain self-contained. The intermediate and final products lent themselves readily to conversion into pharmaceutical and photographic chemicals, technical colloids (viscose, bakelite, etc.), and similar products. The chemical industry must therefore be regarded as a whole, and a new organisation was necessary.

A discussion on atmospheric pollution by smoke concluded the session. Dr. Owens described the apparatus used by the Advisory Committee, and showed records taken at various stations in London, whilst Mr. W. Thomson described the somewhat different apparatus used in Manchester, and exhibited a long series of records from that town. The principal difference noticed was the regular occurrence of a weekly maximum on Monday in the smoke pollution of Manchester, which was never observed in London. That the clearness of the atmosphere during the coal dispute of 1921 was due to the absence of smoke, and not merely to the exceptionally fine weather, was proved by comparing the sunshine records from different parts of the same town. The report of the Fuel Economy Committee, which had a bearing on the same subject, was received, but was not discussed by the section.

The sittings for the reading and discussion of

papers were confined to the mornings, but the section was also occupied in the afternoons. Prof. Barger gave a demonstration in the University of methods for the micro-analysis of compounds containing carbon, hydrogen, and nitrogen, whilst other afternoons were devoted to excursions. Much interest was taken by members in the inspection of the new University chemical laboratories at Liberton, which are arranged as single-story buildings with a central store, the arrangement being convenient and economical, whilst allowing the greatest possible freedom when alterations have to be made. Other visits included the Heriot-Watt College, Messrs. Younger's brewery, the North-British Rubber Co.'s mills, Pumpherstone Oil Works, and the pharmaceutical works of Messrs. Duncan, Flockhart and Co. The rubber works and the shale oil works proved to be specially attractive to members.

Rehtia, the Venetic Goddess of Healing.

AT a meeting of the Royal Anthropological Institute held on January 11 Mr. J. Whatmough read a paper on "Rehtia, the Venetic Goddess of Healing." The Venetic goddess Rehtia (or, as her name might have appeared in Latin, *Rectia*), for whom an apt Greek parallel in name and functions, as well as in characteristic votive offerings, has been found in the Spartan Artemis Orthia, was worshipped not far from the modern town of Este (15 miles south-west of Padua). Her cult, known perhaps to a handful of scholars all told, bears, according to Mr. Whatmough's new explanation of an important group of her offerings, a close likeness to that of the Italic Juno as the protecting goddess of women, with whom Rehtia should be compared rather than, as previously, with the Etruscan Nortia. The group of inscribed votive offerings in question—the so-called "nails" and "wedges"—now better regarded as pins with pendant axe-shaped talismans of a well-known Hallstatt type, was made all but exclusively by women, as the dedicatory inscriptions show. From the shrine of Orthia at Sparta come large numbers of bronze pins, comparable with the Venetic pins which, it is suggested, were given, originally at all events, by women as votive offerings before (or just after) childbirth.

Just as Orthia is expressly described as "The Restorer," or as a healing deity who "restored women to health after childbirth and preserved their infants" (and as such was associated at Epidaurus with Asclepius *Orthios*), so Rehtia is called *Sanatis*, "the Healer," and the word *akeo* which appears on another class of her votive offerings seems also to refer to her healing functions (compare Greek ἀκέομαι). Women paying their vows to Juno Lucina at Rome had to loosen all knots and fastenings about their clothing and take down their hair; it would then be appropriate for them to offer their dress- and hair-pins (or votive objects copied from these) to the goddess. The miniature talismanic axes would imply a magical purpose, the safeguarding of mother and child during gestation and after delivery. With *Sanatis* and *akeo* we can compare such epithets of Juno as Lucina, Februa (Sanatis especially in this connection), Fluonia, and Sospes. It would be a simple step in the development of the goddess (as of Juno) for her to become the saving goddess of both sexes and all classes. The chief duty, however, within her purview would be to maintain or to restore physical health—the soundness, fitness, *rightness* of the body.

Livy, describing events which occurred in 302 B.C. (nearly a century before the beginning of the romanisation of Transpadane Gaul), refers to a temple in the country of the Veneti not far from Padua which he ascribes to Juno; Strabo calls it a temple of the Argive Hera. Most probably the ancient Veneti worshipped a great goddess Rehtia whose functions were similar to those of the Italic Juno and the Argive Hera, so that later observers like Livy and Strabo, familiar with both the more famous Roman and Greek cults, noted the similarities between these and the Venetic cult, and regarded them as essentially the same, if, indeed, we are not further to conclude that with the extension of Greek and Roman religions and civilisations an actual identification had taken place.

Mr. Peake, in discussing Mr. Whatmough's theory, agreed that the bronze objects were not "nails" and "wedges," but pins, though possibly cloak-pins rather than hair-pins, and "axes." The use of the long cloak-pin in the Iron age, when for practical purposes the pin had developed into the fibula, was possibly to be explained by religious conservatism. He also suggested that possibly the wedge-shaped "axe" talisman had developed from the anthropomorphic form of talisman rather than the latter from the former. A third possibility was that they were merely ornaments made to jingle, similar to those common among all horse-loving peoples such as were the invaders of Italy from the north in the Late Bronze and Early Iron ages. While Rehtia could doubtless be equated with Orthia and with Juno, question arose whether the cult was Mediterranean. The Argive Hera is markedly Mediterranean, but Orthia belongs definitely to the northern peoples, as probably did Rehtia. No doubt there had been amalgamation, but the more distinctive features were northern. In their culture some things point to the Veneti being northerners, and probably they were one of the waves of immigration, evidence of the earliest of which was found at Bologna.

British Mycology.

THE Transactions for 1920 of the British Mycological Society published in July last are evidence of the increasing activities of the group of botanists whose work is amongst the fungi. The presidential address by Mr. Petch deals with fungi parasitic on scale-insects, and includes an historical account of the growth of knowledge since the first record of a fungus growing parasitically on a scale-insect was made by Desmazières in 1848 at Caen, in Normandy. The list is now a long one, and will doubtless be further extended; and though the majority of scale-insect fungi are tropical, there is some work to be done on them in the British Isles. In the tropics enormous destruction of scale-insects is effected by these fungi, and, as some of the scale-insects are serious pests of economic plants, the suggestion naturally arose that the pests might be controlled by means of the entomogenous fungi. A special investigation was undertaken by the United States Bureau of Entomology in Florida, but the results agree with those of other experiments, and Mr. Petch affirms that after thirty years' trial there is no instance of the successful control of any

insect by means of fungus-parasites. Prof. A. H. R. Buller describes the mechanism by means of which the common mould-fungus, Pilobolus, is able to shoot its spore-case, containing many thousands of spores, a distance of several feet. Sunlight striking obliquely on the protoplasm of the cell beneath the spore-case gives rise to a stimulus resulting in a movement which places the axis of the stalk on which the spore-case is borne in the line of the light-ray. The fungus may be described as having an optical sense-organ or simple eye which it uses for laying its gun in a definite direction. Pilobolus lives in fields on the dung of herbivorous animals, and by directing its guns towards the source of brightest light is enabled to shoot its sporangia into open spaces on to grass and other herbage. Herbivorous animals eat grass and sporangia together, and the spores are passed unharmed in the solid excreta in which they germinate.

Mr. F. T. Brooks discusses the inheritance of disease-resistance in plants in the light of recent Mendelian work. It has been shown that susceptibility and immunity to yellow rust disease among varieties of wheat are genetic factors operating in a Mendelian way, and Mr. Brooks suggests that resistance and susceptibility of potatoes to wart disease may afford a similar case. He points out, however, that we are very much in the dark as to what is the essential factor conferring resistance, and the possibility that changed conditions of environment may break down to some extent the resistance-powers of the host as regards certain diseases. There are also short papers of local interest and on new or rare British species. Mr. Ramsbottom explains the "Californian bees," the identity of which has been puzzling folk during the past two years. The organism is the well-known ginger-beer plant which was investigated by the late Prof. Marshall Ward, and consists of two organisms, a yeast and a bacterium, living in symbiosis and causing alcoholic fermentation in a sugary solution.

University and Educational Intelligence.

CAMBRIDGE.—A special Syndicate appointed to consider possible alterations in the regulations for the Mathematical and Natural Sciences Tripos with the object of facilitating the acquisition by candidates in one subject of a knowledge of the other has reported in favour of the addition of mathematics to the list of subjects for the Natural Sciences Tripos, Part I. Arrangements are proposed by which part of the papers set in the Mathematical Tripos, Part I., may be used as papers in the Natural Sciences Tripos, Part I. The reform will be of considerable assistance to students reading physics, physical chemistry, and chemistry.

LONDON.—The Senate has received with great satisfaction a communication from the executors of the late Sir Ratan Tata intimating their continuance for a further period of five years of his benefaction of 1400*l.* a year to the Ratan Tata Foundation. This will henceforth be administered as a distinct department by the London School of Economics.

The following doctorates have been conferred:—*D.Sc.* (*Economics*): Mr. T. E. G. Gregory, an internal student, of the London School of Economics, for a thesis entitled "Tariffs: A Study in Method." *D.Sc.* (*Chemistry*): Mr. S. C. Bradford, an external student, for a thesis entitled "On the Theory of Gels," and other papers; and Mr. E. B. Maxted, an external student, for a thesis entitled "The Influence of Inhibitants on the Occlusion and Activation of Hydrogen by Palladium and Platinum," and other papers.

MANCHESTER.—The executors of the late Mr. Hermann Woolley, who was for many years treasurer of the University, have given a donation of 1000*l.* towards the endowment of a lectureship in pharmaceutics.

The following appointments have been made:—Reader in geography, Mr. W. H. Barker, of University College, Southampton; assistant lecturer in physics, Mr. W. S. Vernon; and assistant lecturer in chemistry (technology), Mrs. M. B. Craven.

OXFORD.—The Romanes lecture for 1922 will be delivered at 6 p.m. on May 24 in the Sheldonian Theatre by Prof. A. S. Eddington, Plumian professor of astronomy at Cambridge and president of the Royal Astronomical Society. The subject will be "The Theory of Relativity and its Influence on Scientific Thought."

On January 31 Congregation rejected by 65 votes to 62 the preamble of a statute by which it was proposed to discontinue the Delegacy of the University Museum, and to establish in its place a Board consisting of the heads of the departments of natural science in the University. The opinion of the teachers of science was divided on the question, some, both of the professors and of the college tutors, being opposed to the change. It is, however, probable that there is an almost general conviction that the present constitution of the Delegacy is capable of amendment, though the particular scheme of reform proposed by the Council did not commend itself to the majority. The statute was introduced by the Rev. G. B. Cronshaw, fellow of Queen's, and was supported by Sir C. S. Sherrington and Prof. W. H. Perkin and by the president of Magdalen. It was opposed by Mr. H. B. Hartley, fellow of Balliol, and by Mr. N. V. Sidgwick, fellow of Lincoln.

FIELD-MARSHAL LORD HAIG has been elected Chancellor of the University of St. Andrews in succession to the late Lord Balfour of Burleigh. Lord Haig was elected Rector of the University in 1917, and the office of Chancellor, to which he has now succeeded, is held for life.

ON Wednesday, February 8, at the Sir John Cass Technical Institute, Aldgate, E.C., Prof. W. Rothenstein, principal of the Royal College of Art, will distribute the prizes and certificates gained by the students during the past session and give an address on "Education and Industry."

TWO Theresa Seessel research fellowships at Yale University are being offered, the object of which is the promotion of original research in biological studies. Applications for the fellowships, which are each of the value of 300*l.*, should be made to the Dean of the Graduate School, New Haven, Conn., U.S.A., before May 1 next, accompanied by reprints of scientific publications, letters of recommendation, and a statement as to the particular problem which the candidate expects to investigate.

IT is announced in the *British Medical Journal* that three Canadian universities—Toronto, Western, and Queen's—are co-operating with the Ontario Medical Association in a scheme similar to that adopted by the University of Bristol to keep medical practitioners in outlying districts in touch with recent developments in medicine by means of extension courses. The province has been divided into ten sections, and at a central point in each it has been arranged to hold various courses and give lectures covering a period of six weeks in each year. The courses have already commenced and have proved very popular, many practitioners travelling hundreds of miles to attend them.

Calendar of Industrial Pioneers.

February 2, 1876. Evan Leigh died.—The author of many improvements in cotton machinery and the writer of "The Science of Modern Cotton Spinning" (1871), Leigh was also known as one of the earliest advocates of twin-screw propellers for steamships.

February 2, 1906. Samuel Cunliffe Lister, first Baron Masham, died.—A worsted spinner and manufacturer, Lister took out more than 150 patents, among them being his wool-combing machines and his method of utilising silk waste. The wool-combing machine of the 'fifties cheapened cloth, advanced Bradford's prosperity, and created the Australian wool trade, while by his second great invention he converted what was regarded as useless into a valuable and beautiful material. He was raised to the peerage in 1891.

February 2, 1913. Carl Gustav Patrik de Laval died.—Born at Blosenberg, Sweden, in 1845, de Laval graduated at Upsala University, engaged in practical work, and in 1875 became engineer to the Klosterverken Iron Works. A year or two later he brought out his cream separator, an apparatus now in use throughout the world. Turning his attention to the invention of a steam turbine, he first applied the use of diverging nozzles, discs rotating at a great velocity, and high-speed tooth-gearing. In 1897 he exhibited a turbine supplied with steam at 1500 lb. pressure.

February 3, 1893. James Edward Henry Gordon died.—An original investigator, Gordon worked in Maxwell's laboratory at Cambridge, and in 1880 published "A Physical Treatise on Electricity and Magnetism." He afterwards became connected with some of the pioneer electrical installations in London.

February 4, 1882. Sir William Palliser died.—While an undergraduate at Cambridge Palliser began his study of rifled ordnance and projectiles, and afterwards, when in the Army, became known for his invention of a method of converting smooth bores into rifled guns and his introduction of chilled cast-iron shot.

February 4, 1884. George Auguste Leschot died.—An eminent Swiss horologist, Leschot was one of the first to introduce machinery for making the parts of watches and to make such parts interchangeable. He was also the first to propose the use of the black diamonds of Brazil for the boring of rocks, and with another Geneva mechanician made the first diamond-pointed drill.

February 6, 1877. George Parry died.—Though commencing life as a grocer's assistant, Parry studied the chemistry of iron manufacture, and in 1848 became chemist to the Ebbw Vale Works, where he worked at the utilisation of waste gases, tried Nasmyth's idea of puddling with steam, and made many early experiments in connection with the Bessemer process.

February 7, 1866. David Elder died.—One of the earliest builders of marine steam engines, Elder in 1821 became manager to Robert Napier at Camlachie. He introduced many improvements in his engines, and was one of the first to use steam expansively.

February 7, 1879. Bennet Woodcroft died.—The son of a Lancashire merchant and a pupil of Dalton, Woodcroft became a silk and muslin manufacturer and made valuable improvements in looms and patented various forms of screw propellers. From 1847 to 1851 he was professor of machinery in University College, London, and on the passing of the important Patents Act of 1852 became superintendent of patent specifications. In 1864 he became Clerk to the Commissioners of Patents. He was mainly responsible for starting the Patent Office Library and the Patent Office Museum. E. C. S.

Societies and Academies.

LONDON.

Royal Society, January 26.—Sir Charles Sherrington, president, in the chair.—W. A. **Bone**, A. R. **Pearson**, E. **Sinkinson**, and W. E. **Stockings**: Researches on the chemistry of coal. Pt. 2: The resinic constituents and coking propensities of coals. Prolonged extraction of eight selected coals by typical resin-solvents in a Soxhlet apparatus has no appreciable effect upon their coking propensities, which therefore cannot be ascribed to the presence of free resins. A resin isolated by a new method from two typical bituminous coals has a molecular weight of about 450, agreeing with the empirical formula $C_{31}H_{32}O_3$; its properties correspond with those of a resene in Tschirch's classification of resins. The usual pyridine-chloroform method of extracting coals does not effect a complete separation between the resinous constituents and the degradation products of the cellulose of which coal is conglomerated. It yields an admixture of resins with a predominance of non-resinous substances of cellulosic origin, provisionally designated "humic" bodies. These substances may amount to 4 per cent. of the coal substance. The strong coking propensities of some coals are principally due to the presence, or formation in them by heat, of such non-resinous "humic" substances of cellulosic origin the fusion temperatures of which are below those at which they undergo rapid decomposition; the more complex substances of cellulosic origin, which form the main portion of the coal substance and decompose without fusion, have little or no influence upon the coking properties.—J. A. **Crowther** and B. J. **Schonland**: The scattering of β-rays. The scattering of a homogeneous beam of β-rays has been measured for various elements, and at various angles with the beam. The results obtained are compared with the nuclear theory of scattering of Sir Ernest Rutherford, a correction being applied to allow for the variation of the mass of the β-particle with velocity. Scattering is due to single encounters between the β-particle and the deflecting particles as postulated by the theory until the thickness of the scattering material reduces the radiation to half value. The scattering by gold is in numerical agreement with the theory when measured at very small angles with the primary beam. It increases rapidly as the angle is increased, and finally attains a value approximately four times that given by the theory. This high value is given by the lighter elements at all the angles investigated. Present theories of scattering require modification when the collisions between the β-particle and the deflecting nucleus are closer than a certain critical distance which is of the order of 10^{-10} cm. in the case of gold.—Ann C. **Davies**: The minimum electron energies associated with the excitation of the spectra of helium. The lines of the orthohelium and parhelium series are simultaneously excited when ionisation of the helium atom has occurred. The limiting voltages for excitation are 20·4 and 25·2, according to whether ionisation by multiple impacts can occur or not. The corresponding voltages in the case of the enhanced line $\lambda 4686$ are 54·2 and 80·0 respectively. This line can also be excited from the helium positive ion without further ionisation of the atom at 50·8 volts, the value deduced from Bohr's theory. The minimum voltage for the appearance of the helium band spectrum is 20·4, and the conditions indicate that it is emitted by He_2 molecules. Orthohelium and parhelium lines and the band spectrum are maintained as the voltage is backed down to 13 volts at high pressures.—C. N. **Hinshelwood**, H. **Hartley**, and

B. **Topley**: The influence of temperature on two alternative modes of decomposition of formic acid. Formic-acid vapour in contact with glass surfaces between 200° and 300° C. decomposes mainly in the following ways:—

$$(a)\ H{\cdot}COOH=CO_2+H_2$$
$$(b)\ H{\cdot}COOH=CO+H_2O.$$

The two modes of decomposition proceed at approximately equal rates, but the critical energies calculated from the temperature-coefficients of the respective velocity constants are so different that one reaction should predominate almost entirely unless a phase restriction is introduced. In this case molecules with the necessary critical internal energy do not react at once unless they are in a certain phase.—C. V. **Raman**: The molecular scattering of light in water and the colour of the sea.

Geological Society, January 4.—Dr. G. T. Prior, vice-president, in the chair.—W. D. **Lang**, L. F. **Spath**, and W. A. **Richardson**: Shales-with-beef, a sequence in the Lower Lias of the Dorset coast. Pt. 1: Stratigraphical, by W. D. Lang. The shales-with-beef lie between Table Ledge below and the Birchi Bed above, and consist of an upper 30 ft. of brownish paper-shales with selenite, "beef," and limestone-nodules and lenticles; and a lower 40 ft. of bluish conchoidal marls with indurated marl-beds, beef, and limestone-nodules and lenticles. The main palæontological divisions were given. Pt. 2: Notes on the ammonites, by L. F. Spath. The genera of ammonites found in the shales-with-beef are recorded, and remarks made on their classification and phylogeny. Pt. 3: Petrological Notes, by W. A. Richardson. During sedimentation, calcium carbonate gradually accumulated in solution in the water-logged deposit, and a system of limestones and calcareous nodules was precipitated rhythmically during the initial stages of desiccation. Later, veins of fibrous calcite were deposited at levels of low pressure. On the final drying of the deposit the remaining solutions of calcium carbonate were ultimately deposited as a cementing material.

Optical Society, January 12.—Mr. R. S. Whipple, president, in the chair.—C. J. **Peddle**: The manufacture of optical glass. The history of the manufacture of optical glass can be divided into four epochs, Guinand's discovery of the stirring process in 1796, the work of Abbe and Schott about 1882, and the development in England during the great war being the outstanding features in this history. The method of manufacture is practically the same at the present time as in Guinand's day, any improvement being one of degree rather than of kind. For successful production of the various types the effects of composition upon density, refractive index, melting properties, durability, freedom from colour, and devitrification tendencies have to be studied upon a small scale and the results translated into terms suitable for works practice.—J. W. **French**: The Barr and Stroud 100-ft. self-contained base range-finder. This range-finder has a new type of triple field. It is carried upon a mounting comprising two trucks running upon a roller path of 50 ft. diameter, the trucks being connected by a rigid horizontal framework. Upon the trucks are carried cantilevers, from the ends of which are suspended cradles having special bearings within which the range-finder rests. Training is done by power or by hand. During extensive tests the uncertainty of observation at a range of 31,000 metres did not exceed 20 metres.—T. **Smith**: The optical three-apertures problem. In such an instrument as a submarine periscope, where broad beams of light have to be transmitted down a long tube from a wide field, the relation between the length and diameter of the tube and the number of lenses is considered. Various types of construction are indicated, together with the relative advantages offered by them.

SHEFFIELD.

Society of Glass Technology, January 18.—Dr. M. W. Travers, president, in the chair.—W. L. **Baillie**: An examination and extension of Zulkowski's theory of the relation between the composition and durability of glass. Zulkowski's theory assumes that the essential reactions involved in the founding of glass are the formation of simple silicates of the alkalies and alkaline earths which combine to form double silicates. In these reactions the bases are regarded as competing equally for the acids, and it is assumed that all the materials of the batch enter completely into reaction. If one type of base be molecularly in excess, simple silicates remain in the glass, and are regarded as the prime cause of instability. The difference between Zulkowski's original theory and that now proposed is essentially in the different quantities deduced for the number of molecules of simple silicates present. The term "basic excess" is replaced by a more complete function, for which the term "reactivity coefficient" is suggested. Glasses of satisfactory resistance have reactivity coefficients of under three units. Negative values were generally associated with the most stable glasses, though very large negative values are probably undesirable.—W. E. S. **Turner**: A critical note on the methods of determining the durability of glass. The method of stating the loss in weight due to the attack of reagents is not a trustworthy check. It is better, where possible, to determine either the amount of alkali liberated or the total weight of matter extracted. With boiling reagents flasks gave different results from beakers, and results differed according to the weight or volume of the reagent they contained; pieces immersed gave results different from those obtained where one surface only was in contact with the reagent. Four modes of testing were discussed:—(a) The static method with flasks and beakers, (b) the use of slabs and discs immersed in the reagent, (c) the autoclave test, and (d) a rapid method by grinding glass to pass mesh 20–30. The autoclave test was regarded as uncertain. For speed and convenience test (d) was advocated.—Miss C. M. M. **Muirhead** and W. E. S. **Turner**: The effect of magnesia on the durability of glass. Lime and magnesia glasses were compared. Resistance to attack by water was determined from tests on glass crushed to mesh 20–30 and boiled for one hour. The amount of sodium oxide set free was greater in the case of the lime glasses than in the case of the magnesia glasses. The results of tests on boiling discs in hydrochloric acid for six hours showed that a glass containing small amounts of magnesia was more resistant than the corresponding lime glass, but the difference between the resistance of the glasses is small when they contain 8 or more per cent. of lime or magnesia. Magnesia glasses are less resistant than lime glasses to attack by both sodium carbonate and caustic soda after boiling for three hours.

PARIS.

Academy of Sciences, January 16.—M. Emile Bertin in the chair.—The president announced the death of M. Ciamician, foreign associate.—F. E. **Fournier**: The relations between the form of the hull of a ship, the relative displacements of its satellite wave, its aptitude for speed, its most economical speed, and the resistance of the water to its translation.—C. **Guichard**: The Ω_{00} networks.—P. **Montel**: An exten-

sion of a theorem of M. Landau.—M. **Auric**: The generalisation of complex integral numbers.—M. **d'Ocagne**: The reduction of the fourth dimension to a plane representation.—G. **Tzitzéica**: Networks of points.—P. **Salet**: The pressures of the atmospheres of the stars and the sun. The iron lines of the types *a*, *b*, *c*, *d* of Gale and Adams being unequally displaced towards the red by the effect of pressure, and this displacement being sensibly proportional to the pressure, it is possible, measuring only the difference of displacement of lines of different types, to determine the pressure of the medium in which the lines are produced. The spectra of Procyon, Arcturus, and the sun have been studied from this point of view, and it has been found that the pressures of the atmospheres of the two stars are very slightly higher (1 to 2 atmospheres) than that of the sun. The pressure of the reversing layer of the sun would appear to be only some tenths of an atmosphere.—E. **Brylinski**: An interpretation of Michelson's experiment.—H. **Chaumat**: The application of the ballistic galvanometer to the testing of iron.—G. **Claude**: The accidents observed in the synthesis of ammonia by hyperpressures and on the means of avoiding them.—M. **Taffin**: Annealing and the mechanical properties of glass. The phenomenon of annealing of glass would appear to be only a viscous deformation under the action of internal stresses.—P. **Woog**: The velocity of extension of thin layers of oil on the surface of a sheet of water. From experiments on mineral and fatty oils a connection is traced between the velocity of extension of the oil film on water and the acidity, carboxyl groups of the glycerides, double linkages, and viscosity.—A. **Kling** and Mme. A. **Lassieur**: An apparatus for the determination of the concentration of a solution in hydrogen ions. Application to the detection of mineral acids in vinegar. A compensation method dispensing with the usual standard cell and capillary electrometer and making use of a millivoltmeter.—E. **Grandmougin**: Diphenylsulphone. Considerable quantities of diphenylsulphone, formed as a by-product during the sulphonation of benzine, were accumulated during the war. The author gives an account of some derivatives made with a view to their possible utilisation in the dye industry.—P. **Lemay** and L. **Jaloustre**: Some oxydasic properties of thorium-X. Thorium-X acts as a powerful catalyst in the oxidation of adrenaline and of morphine; on the other hand, no oxidation of the alcohols of the fatty series could be proved.—M. **Muguet**: Lead in the uranium minerals of Madagascar. In the course of the extraction of radium from the Madagascar mineral betafite, lead has been isolated in quantities representing about 0·6 per cent. of the mineral treated. This lead probably arises from the atomic disintegration of uranium; its radioactivity has increased regularly for six months.—M. **Leriche**: Vestiges of the Lutetian in the Quaternary of the north of France.—C. **Jacob**: The structure of north Annam to the north of Thanh Hoa.—L. **Joleaud**: The age of the calcium phosphate deposits of southern Morocco, Algeria, and Tunis.—H. **Joly** and N. **Laux**: The fauna of the middle and upper layers of the Aalenian of the Grand Duchy of Luxemburg.—A. **Boutaric**: The diurnal radiation of the atmosphere at Mont Blanc.—C. **Dufour**: Values of the magnetic elements at the Val-Joyeux station at Villepreux (Seine-et-Oise) on January 1, 1922.—M. **Bridel**: The presence of a glucoside giving rise to an essential oil in the stems and roots of *Sedum telephium*. The glucoside extracted from this plant hydrolysed with emulsin gives glucose and an essential oil smelling of roses. Hydrolysed with dilute sulphuric acid the essential oil undergoes a change, and the smell resembles eucalyptol or terpineol.—A. **Goris** and H. **Deluard**: The influence of solar radiation on the culture of belladonna and the formation of alkaloids in the leaves. Insolation favours the production of alkaloids in the leaves of belladonna, and also the size of the leaves.—C. **Oberthür** and C. **Houlbert**: Some new views on the classification of the Melanargia (Lepidoptera: Satyridæ).—C. **Champy**: The determination of the sexual characters in Tritons. A criticism of some views expressed by Bouin and Ancel.—B. **Roussy**: Measurement of the cutaneous surface of the horse.—M. **Marage**: Acuteness of hearing and aptitude for military service. Deafness alone should not be a cause of rejection for army service, a person entirely deaf being still capable of rendering service to the army in a suitable position.—J. **Dragoui**: The influence of osmotic pressure on cell division.—S. **Metalnikow**: Sterile death in infected caterpillars. Under certain conditions the phagocytes are successful in removing all the foreign organisms (cholera, sarcina, staphylococcus), but the caterpillar dies, although sterile.—M. **Schein**: The possible duality of aphthous fever.—H. **Vallée** and H. **Carré**: Anti-aphthous immunity.

BRUSSELS.

Royal Academy of Sciences, January 7.—M. Aug. Lameere in the chair.—H. **Lonay**: Contribution to the study of the relations and structure of the different parts of the ovule and of its general nutrition before and after impregnation.—P. **Bruylants**: Contribution to the study of the reaction of the organo-magnesium compounds on nitriles.

WASHINGTON, D.C.

National Academy of Sciences, Proceedings, vol. 7, No. 1 (January, 1921).—A. **Van Maanen**: Internal motion in the spiral nebula Messier 33. It is shown that the motion is along the arms of the spiral and is not a rotation of the nebula as a whole. The magnitude of the motions would indicate that the nebula is not comparable in dimensions with the galactic system.—L. B. **Loeb**: The attachment of electrons to neutral molecules in air. The mechanism of negative-ion formation in air lies in the electron attaching itself to the molecule to form the negative ion on the average in one out of 250,000 molecular impacts. It is to the oxygen molecule that the electron is attached.—F. G. **Benedict**, M. F. **Hendry**, and M. L. **Baker**: The basal metabolism of girls twelve to seventeen years of age. The basal heat production per kilogram of body-weight per twenty-four hours decreases regularly with increasing age from 30 Calories at twelve years to nearly 22 Calories at seventeen years.—R. A. **Millikan** and I. G. **Barber**: The reflection and re-emission of electrons from metal surfaces and a method of measuring the ionising potential of such surfaces. Contrary to current belief, there appears to be no such phenomenon as the direct reflection of an electron from a copper surface.—E. H. **Morris**: Chronology of the San Juan area. The establishment of a chronological scale for the area of San Juan gives us a succession of cultural periods during the greater part of the prehistoric period for the south-west.—W. **Bowie**: Some geologic conclusions from geodetic data. Geodetic evidence indicates that land masses are in isostatic equilibrium and that the equilibrium exists in a comparatively small area. It is inferred that land masses have been in equilibrium in former geologic periods, and that mountain systems formed in previous sedimentary areas are due to expansion of the material under them.—D. P. **Smith**: Experiments on the electrical conduction of a hydrogen alloy. The temporary supple-

mentary conduction exhibited by metals during the cathodic occlusion of hydrogen is not of ordinary metallic character.—J. A. **Harris** and E. W. **Sinnott**: The vascular anatomy of normal and variant seedlings of *Phaseolus vulgaris*. A comparative and biometric study of the gross vascular anatomy of the seedlings.—L. L. **Woodruff**: The present status of the long-continued pedigree culture of *Paramecium aurelia* at Yale University. The culture has attained to about 8900 generations during thirteen and a half years of life. Conjugation is not necessary, but there is a periodic endomyxis.

No. 2 (February, 1921).—A. J. **Dempster**: Positive-ray analysis of magnesium. Isotopes of weights 24, 25, and 26 combined in the ratio 1 : 1 : 6 are found.—C. **Barus**: The energy content of the diapason.—W. A. **Setchell**, T. H. **Goodspeed**, and R. E. **Clausen**: A preliminary note on the results of crossing certain varieties of *Nicotiana Tabacum*. One general result has been a demonstration of the difference from a genetic point of view between any two of a number of so-called fundamental varieties of *N. Tabacum*.—J. **Kendall**: The correlation of compound formation, ionisation, and solubility in solutions: Outline of a modified ionisation theory. It is assumed that ionisation is preceded by combination between solvent and solute, and is indeed a consequence of such combination.—E. H. **Hall**: The Peltier effect. Application of the author's recently proposed theories of electrical conduction on metals to the discussion of the Peltier effect.—J. H. **McDonald**: The roots of Bessel's functions.

Diary of Societies.

THURSDAY, FEBRUARY 2.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Napier Shaw: Droughts and Floods (1).

ROYAL SOCIETY, at 4.30.—C. Shearer: The Oxidation Processes of the Echinoderm Egg during Fertilisation.—J. Schmidt: The Breeding Places of the Eel.—J. Gray: The Mechanism of Ciliary Movement.—J. Gray: The Mechanism of Ciliary Movement. Parts 1 and 2.—J. S Huxley and L. T. Hogben: Experiments on Amphibian Metamorphosis and Pigment Responses in Relation to Internal Secretions.

LINNEAN SOCIETY OF LONDON, at 5.—F. Johanssen: The Canadian Arctic Expedition.—Dr. J. C. Willis and U. Yule: Some Statistics of Evolution and Distribution in Plants and Animals, and their Significance.—Mrs. E. M. Reid: Note on Fossil Floras.

ROYAL SOCIETY OF MEDICINE (Medicine Section), at 5.—Sir William Hale-White, Sir William Willcox, Sir Berkeley Moynihan, and Mr. Sherren: Discussion: The Treatment of Gastric Ulcer.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—L. J Romero and J. B. Palmer: The Interconnection of A.C. Power Stations.

CHEMICAL SOCIETY, at 8.—E. J. Hartung: The Action of Light on Silver Bromide.—C. K. Ingold: The Structure of the Benzine Nucleus. Part I. Intra-nuclear Tautomerism.—C. K. Ingold: The Structure of the Benzine Nucleus. Part II. Synthetic Formation of the Bridged Modification of the Nucleus.—C. K. Ingold and H. A. Piggott: The Structure of the Benzine Nucleus. Part III. The Suppression of Intra-nuclear Change.

FRIDAY, FEBRUARY 3.

INSTITUTE OF COST AND WORKS ACCOUNTANTS (at Holborn Restaurant), at 2.30.—Costing Conference on the Necessity for Scientific Costing.

ROYAL SOCIETY OF MEDICINE (Laryngology Section), at 4.45.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. K. M. Walker: The Nature and Cause of Old Age Enlargement of the Prostate (Hunterian Lecture).

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—H. S. Denny and N. V. S. Knibbs: Some Observations on a Producer-gas Power Plant.

EUGENICS EDUCATION SOCIETY (at Royal Society), at 8.—Prof. H. J. Fleure: Some Social Bearings of Race Study.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—Major W. Gregson: Utilisation of Waste Heat from Internal Combustion Engines.

ROYAL SOCIETY OF MEDICINE (Anæsthetics Section), at 8.30.—Dr. A. L. Flemming and others: Discussion: The Uses and Limitations of N_2O and O_2 Anæsthesia.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir Francis Younghusband: The Mount Everest Expedition.

MONDAY, FEBRUARY 6.

VICTORIA INSTITUTE (at 1 Central Buildings, Westminster, S.W.1), at 4.30.—Dr. A. T. Schofield: Some Difficulties of Evolution.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. A. H. Todd: Orthopædic Aspects of Rheumatoid Arthritis (Hunterian Lecture).

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.—General Meeting.

SOCIETY OF ENGINEERS, INC. (at Geological Society), at 5.30.—T. J. Gueritte: Presidential Address.

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting), at 7.—J. Joseph and others: Discussion: Some Practical Applications of the Thermionic Valve.

ARISTOTELIAN SOCIETY (at University of London Club, 21 Gower Street, W.C.1), at 8.—A. H. Hannay: Standards and Principles in Art.

ROYAL SOCIETY OF ARTS, at 8.—C. Ainsworth Mitchell: Inks (Cantor Lectures) (3).

SOCIETY OF CHEMICAL INDUSTRY (London Section) (at Chemical Society), at 8.

SURVEYORS' INSTITUTION, at 8.—Adjourned Discussion on paper by W. R. Davidge: The Problems of Greater London.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.30.—President's Address to Students.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—Brig.-Gen. G. K. Cockerill: Byways in Hunza and Chitral.

TUESDAY, FEBRUARY 7.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. H. H. Turner: Variable Stars (2), Long Period Variables.

ROYAL SOCIETY OF ARTS (Dominions and Colonies Section), at 4.30.—W. Turnbull: The Timbers of British Columbia.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—The Secretary: Report on the Additions made to the Society's Menagerie during the months of November and December, 1921.—A. H. Evans: Some Deductions from a Set of Cuckoo's Eggs taken near Cambridge, and now Exhibited.—Lord Clifford of Chudleigh: *Nototherium mitchelli*.—Miss L. E. Cheesman: (1) Sense-organs of the Fresh-water Crab, *Cardisoma armatum*. (2) Position and Function of the Siphon in the Amphibious Mollusc, *Ampullaria vermiformis*.—C. W. Hobley: The Fauna of East Africa and its Future.—Dr. J. Stephenson: Contribution to the Morphology, Classification, and Zoogeography of Indian Oligochæta.—IV. The Diffuse Production of Sexual Cells in a Species of *Chaetogaster* (Fam. Naididæ). V. *Drawida japonica* (Michlsn.), a Contribution to the Anatomy of the Moniligastridæ. VI. The Relationships of the Genera of Moniligastridæ; with Some Considerations on the Origin of Terrestrial Oligochæta.

INSTITUTION OF CIVIL ENGINEERS, at 6.—Dr. H. F. Parshall: Hydro-electric Installations of the Barcelona Traction, Light, and Power Company.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—O. J. Wilkinson: The Application of Flashlight Photography to the Study of Natural History Subjects.

RÖNTGEN SOCIETY (at Institution of Electrical Engineers), at 8.15.—W. H. Wilson: A New High-tension Generator for X-ray and other work.—H. C. Head: Canny Ryall Diathermy Apparatus; Ionostat; A New Iontoquantimeter; New X-ray Protective Material.—H. E. Donithorne: The Taylor Jones Electrostatic Oscillograph; A New Design of Gold Leaf Electroscope.—C. Andrews: A New Boiling-water X-ray Tube.—F. R. Butt and Co., Ltd.: Diathermy Apparatus.—E. E. Burnside: A New Model of X-ray Table.

WEDNESDAY, FEBRUARY 8.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. A. G. T. Fisher: A Research into the Pathology and Ætiology of Osteo-arthritis, with Observations upon the Principles underlying its Treatment (Hunterian Lecture).

INSTITUTION OF AUTOMOBILE ENGINEERS (at Institution of Mechanical Engineers), at 8.—E. L. Bass: Engine Lubrication.

ROYAL SOCIETY OF ARTS, at 8.—E. V. Evans: Some Solved and Unsolved Problems in Gas Works Chemistry.

MEDICAL SOCIETY OF LONDON (at 11 Chandos Street, W.1), at 9.—Sir Leonard Rogers: Amœbic Liver Abscess: Its Pathology, Prevention, and Cure (Lettsomian Lectures) (2).

THURSDAY, FEBRUARY 9.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Napier Shaw: Droughts and Floods (2).

ROYAL SOCIETY, at 4.30.—*Probable Papers.*—Sir J. A. Ewing: The Atomic Process in Ferro-magnetic Induction.—Prof J. W. Nicholson: Problems relating to a Thin Plane Annulus.—Prof. T. H. Havelock: The Effect of Shallow Water on Wave Resistance.—R. H. Fowler and S. N. H. Lock: The Aerodynamics of a Spinning Shell. Part II.—F. P. Pidduck: The Kinetic Theory of a Special Type of Rigid Molecule.—J. E. Jones: The Velocity Distribution Function and the Stresses in a Non-uniform Rarefied Monatomic Gas.—H. Bateman: The Numerical Solution of Linear Integral Equations.

LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5.—H. Hilton: Conics on the Pseudo-sphere.—W. F. D. MacMahon: The Theory of Closed Repeating Polygons in Euclidean Space of Two Dimensions.—G. H. Hardy and J. E. Littlewood: Dirichlet's Series with a Barrier of Singularities.

INSTITUTION OF CIVIL ENGINEERS (Students' Meeting), at 6.—E. J. Kingston-McCloughry: The Design of Modern Water-turbines.

OPTICAL SOCIETY (at Imperial College of Science and Technology), at 7.30.—Annual General Meeting.—F. W. Preston: The Structure of Abraded Glass Surfaces.—A. J. Dalladay and F. Twyman: The Stress Conditions Surrounding a Diamond Cut in Glass.—Lt.-Col. J. W. Gifford: A Supplementary Note on Achromatic One-Radius Doublet Eyepieces.—F. Twyman and A. J. Dalladay: Change in Refractive Index at the Surfaces of Glass Melts.

CHEMICAL SOCIETY (at Institution of Mechanical Engineers), at 8.—Sir Ernest Rutherford: Artificial Disintegration of Elements.

INSTITUTE OF METALS (London Section) (at Sir John Cass Technical Institute, Jewry Street, E.C.3), at 8.—R. T. Rolfe: Gun-metal.

FRIDAY, FEBRUARY 10.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.—Annual General Meeting.—Dr. E. A. Owen and Bertha Naylor: The Measurement of the Radium Content of Sealed Metal Tubes.—Sir William Bragg: The Crystal Structure of Ice.—Dr. K. Grant: A Method of Exciting Vibrations in Plates, Membranes, etc., Based on Bernouilli's Principle.

ROYAL ASTRONOMICAL SOCIETY, at 5.—Anniversary Meeting.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. A. C. Pannett: Hydronephrosis (Hunterian Lecture).

KING'S COLLEGE ENGINEERING SOCIETY (Anniversary Meeting) (at Institution of Civil Engineers), at 5.30.—F. W. Macaulay: Water Engineering.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—Questions and General Discussion.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. W. D. Halliburton: The Teeth of the Nation.

PUBLIC LECTURES.

(*A number in brackets indicates the number of a lecture in a series.*)

THURSDAY, FEBRUARY 2.

INFANTS' HOSPITAL (Vincent Square, S.W.1), at 4.—Dr. W. M. Feldman: The Physiology and Pathology of Ante-natal and Early Post-natal Life (1).

KING'S COLLEGE, at 5.30.—Dr. O. Faber: Reinforced Concrete (3).

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN (Leicester Square, W.C.2), at 6.—Dr. J. L. Bunch: Drug Eruptions (Chesterfield Lecture).

CIVIC EDUCATION LEAGUE (at Leplay House, 65 Belgrave Road, S.W.1), at 8.15.—Miss Barbara Low: Psycho-analysis in relation to Civics.

FRIDAY, FEBRUARY 3

METEOROLOGICAL OFFICE (South Kensington), at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (3).

UNIVERSITY COLLEGE, at 5.—Prof. G. Elliot Smith: The Evolution of Man (1); at 6.—Miss E. Jeffries Davis: London and its Records.

KING'S COLLEGE, at 5.30.—Rev. Dr. F. A. P. Aveling: Matter, Mind, and Man.—Dr. H. W. Williams: The Peoples of the Caucasus (3).

TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES (at the Mary Ward Settlement, Tavistock Place, W.C.1), at 5.30.—Dr. H. Crichton Miller: The New Psychology and its Bearing on Education (2).

SATURDAY, FEBRUARY 4.

SALTERS' HALL (St. Swithin's Lane, E.C.4), at 10.30 a.m.—Dr. M. O. Forster: The Relation between Pure and Applied Chemistry.

LONDON DAY TRAINING COLLEGE, at 11 a.m.—Prof. J. Adams: The School Class (3).

HORNIMAN MUSEUM (Forest Hill), at 3.30.—E. Lovett: The Folk-lore of Natural History.

MONDAY, FEBRUARY 6.

UNIVERSITY COLLEGE, at 5.15.—Sir Gregory Foster: The University of London: Its History, Present Resources, and Future Possibilities (1).

CITY OF LONDON (BOYS') SCHOOL, at 5.30.—Miss Rosa Bassett: The Dalton Plan of Self-education (1).

KING'S COLLEGE, at 5.30.—Prof. O. L. Fortescue: Wireless Transmitting Valves (3).—Dr. J. Steppat: Recent Developments in German Education and Student Life (3).

TUESDAY, FEBRUARY 7.

KING'S COLLEGE, at 5.30.—F. H. Rolt: Accurate Measurements in Mechanical Engineering: The Use and Testing of Gauges (2).

WEDNESDAY, FEBRUARY 8.

SCHOOL OF ORIENTAL STUDIES, at 5.—W. Doderet: Racial Types in the Bombay Presidency.

HORNIMAN MUSEUM (Forest Hill), at 6.—W. W. Skeat: The Living Past in Britain (3).

THURSDAY, FEBRUARY 9.

UNIVERSITY COLLEGE, at 5.15.—Prof. J. E. G. de Montmorency: Welsh and Irish Tribal Customs (1).

KING'S COLLEGE, at 5.30.—Dr. O. Faber: Reinforced Concrete (4).—M. Beza: Nereids in Roumanian Folk-lore.

TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES (at the Mary Ward Settlement, Tavistock Place, W.C.1), at 5.30.—Dr. H. Crichton Miller: The New Psychology and its Bearing on Education (3).

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN (Leicester Square, W.C.2), at 6.—Dr. W. Griffith: The Skin Eruptions of Syphilis (Chesterfield Lecture).

FRIDAY, FEBRUARY 10.

METEOROLOGICAL OFFICE (South Kensington), at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (4).

SATURDAY, FEBRUARY 11.

LONDON DAY TRAINING COLLEGE, at 11 a.m.—Prof. J. Adams: The School Class (4).

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Miss M. A. Murray: The Domestic Life of the Ancient Egyptians.

British Water Power and its Administration.

FOLLOWING almost immediately upon the publication of the Third and Final Report of the Water Power Committee of the Conjoint Board of Scientific Societies, there has recently appeared the Final Report of the Water Power Resources Committee of the Board of Trade. To a certain extent it may be said that the two Reports cover common ground, but there is this important distinction, that, whereas the Water Power Committee of the Conjoint Board addressed itself to the widest possible survey of the resources of the British Empire, the Board of Trade Committee has been limited by its terms of reference to the resources of the United Kingdom. The investigations, therefore, of the latter body within this restricted area have naturally been more searching and more detailed, and to that extent more complete.

The Report of the Board of Trade Committee confirms, in general, the views which were expressed in a leading article in NATURE of December 8 last in reviewing the earlier Report, particularly as regards the necessity of conserving the national resources of water power, of taking steps without delay to ascertain accurately their full extent and availability, and of providing effectively for their economic and judicious development in the interests of industrial enterprise. The Committee states, as a result of its researches, that it is estimated by the development of certain specified water-power schemes in Great Britain (a by no means exhaustive list) that a continuous output of 210,000 kilowatts could be obtained at an economic rate, and that this would result in a saving in coal consumption for steam-raising purposes of nearly three million tons per annum.

The statement is impressive as an instance of the prodigality with which the country's power resources are allowed to run to waste. But while the desirability of effecting so appreciable a reduction in the national coal bill must be clear and unmistakable to all who give a thought to the matter and realise the limitations of our stores of solid fuel, yet the suggestion put forward in the present Report as to the primary step to be taken towards this end will perhaps not receive such unquestioning assent. The Committee, with two dissentients, recommends the establishment by Act of Parliament of a Water Commission with controlling powers over the water resources of England and Wales, and authority to compile proper records, to allocate supplies, to adjust conflicting interests, and to recommend suitable development schemes. The public, restive after a long and irksome imposition of bureaucratic control, will, we feel, be inclined to express sympathy with the minority view of Mr. Sandford Fawcett and Mr. W. A. Tait that the appointment of such a Commission is unnecessary, and that it must necessarily prove a source of further expense to the taxpayer. Mr. Tait, in his separate memorandum on the proposal, utters a justifiable warning on the inherent defects of a permanent official body vested with statutory powers. "Such a Commission," he says, "however well constituted and however open-minded its members at first may be, will inevitably in course of time become bureaucratic in its outlook, and will in this respect be less fitted to adapt itself to circumstances, as these vary from time to time, than independent Committees of Parliament, who, from the nature of things, approach any subject with fresh minds and unbiased views."

We confess that, to a considerable extent, we share Mr. Tait's apprehensions. There is undoubtedly a tendency on the part of all official bodies to become stereotyped and perfunctory. Imbued with a sense of immunity from criticism, they not infrequently adopt autocratic methods, and this does not endear them to the public mind. For our own part, while cordially agreeing as to the urgent desirability of carrying out each and all of the functions and duties enumerated for the proposed Commission, we are inclined to suggest that the collection and col-

lation of data could be assigned at less expense to some existing department, such as the Ordnance Survey, as is the case in the United States, where the work is carried out by the Geological Survey, and that as regards jurisdiction and oversight of sources of supply these could be exercised without undue strain by County Councils or similar provincial bodies, while sanction for new schemes in the public interest should be obtained by application to Parliament in the customary way by private Bill as at present. We see no occasion for departmental initiative in industrial enterprise. Such a policy leads to the preparation of grandiose and untimely projects like that recently put forward for the River Severn by the Ministry of Transport. British commercial enterprise is not dead, and if a scheme be reasonably practicable and remunerative it is sure to receive support. We therefore range ourselves alongside Mr. Fawcett and Mr. Tait in deprecating the creation of an additional Government department with a retinue of salaried officials. There is a significant suggestion in the Report that the expenses of the proposed Commission should be defrayed *in part* by a levy on water undertakings in England and Wales. We imagine that this will give rise to some demur.

Into the more detailed recommendations of the Committee we do not feel it necessary to enter at the moment. The Report is a lengthy one, running to 165 foolscap pages, with maps and diagrams. In addition to the primary and principal recommendation, upon which we have commented above, there are subsidiary recommendations, such as that all hydrometric data collected in the United Kingdom should be compiled on a uniform basis (a schema is exhibited in an appendix), and that the widest publicity should be given to the information obtained in these surveys. With both these suggestions we are in complete accord. There is also the interesting statement that, "leaving out of account the question of availability, the schemes in our possession relate to potential water-power of a total capacity in excess of 250,000 kw. (continuous). The aggregate power involved in the various parts of Great Britain is as follows: Scotland, 194,965 kw.; Wales, 35,900 kw.; England, 20,440 kw. The Irish Sub-Committee estimates that the total available potential water-power resources of Ireland amount to 280,000 kw. (continuous)."

The purview of the Report is comprehensive and includes a consideration of tidal power, canals, salmon fisheries, pollution of underground water, and land drainage. We do not propose to discuss these features. Our immediate object will be achieved if we succeed in focusing attention on the urgent necessity for a systematic compilation of the water resources of the country and of the Empire, to be followed by some means of ensuring a judicious application of the available power in the most economical manner so as to reduce the present excessive demands on our reserves of solid fuel.

American Organic Chemicals.

THE production of synthetic organic chemicals for use in research is being developed in America on the same lines as in this country. Laboratories have been specially equipped for the purpose by the Eastman Kodak Company, which makes a number of compounds and purifies others yielded by the chemical industry of the country. In that way some eleven hundred different chemicals are at present available. Although this is only half the number of substances offered by one of the English manufacturers, the effort is meeting with enthusiastic support from men of science in America, and those concerned feel thereby greatly helped and encouraged. In that country, at least, the war-time resolution of independence in the matter of scientific supplies is not forgotten.

Much complaint is made in this country concerning the prices of such chemicals. It is therefore of interest to compare Kahlbaum's pre-war prices and the present prices of a well-known English manufacturer with those of the Eastman Kodak Company. A comparison extending to four pages of the Eastman list gives the ratio: Kahlbaum, 100; B.D.H., 135; Eastman, 171—not so great an increase on pre-war prices as the increase in cost of labour would lead one to expect.

In a paper read before the Society of Chemical Industry last August, C. E. K. Mees and H. T. Clarke gave some account of the chemical work of the Eastman Company. They said it had been conducted hitherto at a very considerable loss, the first year's working showing a deficit of about 3000*l.*, although no rent or overhead charges were debited. This loss was generously borne by the company.

If American users and producers continue to work in the same spirit, not only will they gain the immense advantage of national independence in the matter of organic chemicals, but also the business will become self-supporting and in the end remunerative. At the same time, laboratories in which such organic compounds are made should provide a useful training-ground for young technical chemists.

Elie Metchnikoff.

Life of Elie Metchnikoff, 1845–1916. By Olga Metchnikoff. Authorised translation from the French. Pp. xxiii + 297. (London: Constable and Co., Ltd., 1921.) 21*s*. net.

In an introductory chapter Madame Metchnikoff relates how, some years ago, one who scarcely knew her husband had asked permission to write his biography. Metchnikoff wanted his biography written, for he held that the story of the evolution of a mind and character in relation with its environment, if faithfully set down by one knowing and comprehending, is always an interesting psychological document. The idea of the story of his life being related by one who neither knew nor understood was, however, repugnant to him. So it came about that Madame Metchnikoff undertook the biography of her husband with his co-operation and on the understanding that the whole was to be told without reservation. The result, as Sir Ray Lankester observes in an appreciative preface to the English edition, is "a remarkable and beautiful record of the development and activities of a great discoverer."

Metchnikoff was born in 1845 in the province of Kharkoff, where he was educated first at the lycée and then at the university. The lycée is represented as a progressive school, and the sketch of the youthful Metchnikoff and his companions affords an interesting glimpse of the intellectual awakening of young Russia at this period. Among the books he read at fourteen years of age was Buckle's "History of Civilisation," and we gather from the biography that the idea of the dependence of human progress upon science originated from reading that work. This belief became strengthened as he grew older, and ultimately it reached the intensity of a religious faith. At fifteen years of age Metchnikoff abandoned the religion in which he had been brought up, and so ardently preached atheism to his fellow-pupils that he received the nickname "God is not." Although he appears to have devoted most of his time at school to reading books on science, religion, and philosophy, he nevertheless passed out from the lycée with the highest honours and entered the university. This is described as a stagnant and reactionary institution. His teachers were uninspiring, and exerted little influence upon him.

While at the university, however, he read "The Origin of Species," which he had brought back with him from a visit to Germany. Metchnikoff was fascinated by the splendour of the horizon it opened, and considered it had more influence upon his later career than any other book he read. He seems to have planned to devote himself to searching for further support of Darwin's great generalisation. With this object he decided to undertake the study of intermediate types with a view to disclosing the genetic relationships between different orders of animals.

This programme could not be carried out at his own university, so as soon as his undergraduate career was completed he went to Germany. Afterwards he removed to Naples, where he met Kowalevsky. Both young men became engaged in a comparative study of the embryology of invertebrates. Metchnikoff discovered embryonic layers similar to those of vertebrates in Arthropoda and Cephalopoda, thus helping to bridge the gap between the higher and lower animals.

It was at Giessen in 1865 that intracellular digestion by the cells of the alimentary canal of a land-planarian (*Geodesmus bilineatus*) was observed. It is explained that this was the first time that he had encountered this phenomenon except in protozoa and very simple metazoa. He was much impressed, and afterwards regarded the observation as the basis of his phagocytic theory, although at the time its full significance was not appreciated.

Returning to Russia full of enthusiasm for science, Metchnikoff was appointed a *docent* at Odessa, but, finding the university backward and reactionary, he removed to St. Petersburg, where he hoped to find conditions for work more congenial. He was, however, disappointed. There was no laboratory for him to work in, his time was consumed by teaching for a subsistence, his eyes became troublesome and his health bad. He was lonely, and during an illness he was nursed by a young lady in the house of a mutual friend. Craving for affection and sympathy, he not unnaturally became engaged to be married.

Unfortunately, the lady was phthisical and developed alarming symptoms immediately after marriage. The next few years are described as a tragic struggle against disease and poverty. The serious affection of his eyes prevented the use of the microscope, and his young wife's health became so precarious that he was obliged to resign his appointment and take her to Madeira, where she died.

After his wife's death Metchnikoff started on the return journey to Russia in blank despair, and, seeing no issue to his situation, attempted suicide at Geneva. Fortunately, he took too large a dose of morphia, was violently sick, and recovered.

On his return to Russia Metchnikoff was appointed to the chair of zoology at Odessa, which he occupied for nine years. He threw himself with enthusiasm into the duties of his post. At Odessa

he met Madame Metchnikoff, who was then a schoolgirl. Finding that she was interested in zoology, he undertook to teach her, and shortly after they married. His second marriage was a happy one; his wife, although more directly interested in art than in science, became a willing disciple. Madame Metchnikoff thus describes their work together:—

"It was both delightful and profitable to work with him, for he opened out his ideas unreservedly and made one share his enthusiasm and his interest in investigations; he could create an atmosphere of intimate union in the search for truth which allowed the humblest worker to feel himself a collaborator in an exalted task."

Metchnikoff appears to have exerted a great influence in the university, especially upon the young men, but was regarded with some suspicion by the authorities, owing to the independence of his ideas and the directness with which they were expressed. After the assassination of Alexander II. in 1881 the government of the university became more and more reactionary, and the independence of the university was threatened. Though not greatly interested in politics, Metchnikoff seems to have become unavoidably involved in these quarrels, and ultimately, finding the conditions intolerable, resigned.

His resignation of the Odessa chair and the circumstances which led to it preyed upon his mind. Another period of ill-health ensued associated with intense depression, during which suicide was again attempted. In order not to harrow his family by a suicide that was too obvious, and at the same time to put the occasion to the use of ascertaining whether relapsing fever could be transmitted by inoculation, he injected into himself some blood from a patient suffering from that disease. He had a prolonged attack of the fever, but this shock treatment cured his pessimism, and after his recovery he had a renascence of vital energy such as he had not enjoyed for years. Moreover, thanks to the inheritance of landed property, the Metchnikoffs were now in a position of modest independence and able to live where they liked. Accordingly in 1882 they repaired to Messina to take advantage of the opportunities for study afforded by the sea fauna of the Mediterranean.

It was at Messina, at Christmas of that year, that what Metchnikoff regarded as the great event of his scientific life occurred. It is described by him in his own words as follows:—

"One day, when the whole family had gone to a circus, I remained alone with my microscope, observing the life in the mobile cells of a transparent starfish larva, when a new thought suddenly flashed across my brain. It struck me that similar cells might serve in the defence of the organism against intruders. I felt so excited that I began striding up and down the room, and even went to the seashore to collect my thoughts.

"I said to myself that, if my supposition was true, a splinter introduced into the body of a starfish larva, devoid of blood-vessels or of a nervous system, should soon be surrounded by mobile cells, as is to be observed in a man who runs a splinter into his finger. This was no sooner said than done.

. . . . .

"I fetched some rose-thorns and introduced them under the skin of some beautiful starfish larvæ as transparent as water.

"I was too excited to sleep that night in the expectation of the result of my experiment, and very early the next morning I ascertained that it had fully succeeded.

"That experiment formed the basis of the phagocyte theory, to the development of which I devoted the next twenty-five years of my life.

. . . .

"A zoologist until then, I suddenly became a pathologist."

It appears that the discovery of phagocytosis first disclosed to him the possibility of utilising his talents to intervene advantageously in human affairs. A moral purpose in life was found, and thenceforth Metchnikoff became an optimist and a scientific philanthropist. His future researches, although conducted in the laboratory, were essentially directed towards the improvement of the health and happiness of mankind. Possibly his scientific work suffered occasionally from his impatience to apply results to the benefit of his fellow-creatures, for, like most philanthropists, he exhibited some intolerance of criticism of his efforts.

In 1882 phagocytosis as a curative force was still only an hypothesis, but an opportunity for putting it to the test of experiment soon occurred. Water fleas (Daphniæ) were observed to be subject to infection by a fungus (*Monospora bicuspidata*) the spores of which, sharp like needles, traversed the gut of the insect when introduced with food. Watching the process in these transparent creatures, Metchnikoff saw that, immediately after the entrance of a spore into the body cavity, it was attacked by mobile phagocytes and englobed. If the phagocytes succeeded in digesting all the spores, the daphnia recovered, otherwise the spores germinated, and the fungus, spreading throughout the body, killed the insect. Recovery or death depended upon the issue of the battle.

The next question to be decided was whether this method of defence was common to all animals. That some diseases of higher animals were attributable to invasion by microbes had recently been established, and it is explained how Metchnikoff's previous training and experience as a zoologist had led to the conviction of the essential unity of structural plan and physiological behaviour throughout

the animal kingdom. Metchnikoff was convinced that in the case of such a fundamental mechanism as that he had discovered in invertebrates this would prove to be true, and shortly afterwards he succeeded in establishing the generality of the phenomenon by experiments upon higher animals infected with the anthrax bacillus. In this case the bacilli were attacked and eaten by the white blood corpuscles which wander everywhere. Two other observations recorded deserve special mention because they opened up new country, the exploration of which occupied Metchnikoff and his pupils and many others for the next twenty years.

The first of these was that active phagocytosis occurred only in animals refractory to anthrax, thus providing a possible interpretation of the natural immunity of some species of animals to a disease. The second was that animals naturally sensitive to anthrax could be induced to respond like naturally refractory ones by vaccination, an indication of the nature of acquired immunity.

Such entirely new conceptions were not readily acquiesced in, and even encountered hostility. Two great men, Virchow and Pasteur, however, were immediately impressed by them, and in 1888 the latter invited Metchnikoff to come to the Pasteur Institute. The invitation was accepted, and there he remained until the end of his life, occupied under ideal conditions in developing the consequences of his discovery at Messina.

At the Pasteur Institute he found every facility for his researches, and was undisturbed by administrative or academic work. He enjoyed the companionship of wise colleagues, themselves actively engaged in inquiries in bacteriology and pathology, and soon became surrounded by willing pupils ready to undertake investigations dictated by his fertile imagination.

This was a time of immense activity, mainly devoted to exploring the whole subject of immunity which he had illuminated by the discovery of phagocytosis. This prolific period of his career is skilfully dealt with in broad outline, and details which, being of a highly technical character, would be tiresome to the general reader are omitted. The theories current regarding immunity when Metchnikoff approached the subject from a naturalist's point of view are briefly sketched, and the influence of his work and that of others in the development of our present views is indicated.

In 1900 Metchnikoff presented an account of his researches to the International Congress of Medicine at Paris, and fought his critics for the last time. Then, convinced that his deductions were sound, he proceeded to expound his views at length under the title, "Immunity in Infectious Diseases," which appeared a few years later.

Metchnikoff's greatest scientific achievement was undoubtedly the discovery of phagocytosis and its manifold significance in biology and pathology, and it is clearly brought out in his biography that he would not have made these discoveries had it not been for his previous training and research in zoology. Perhaps the best way to appraise this, his contribution to science, is to try to think what our present knowledge of inflammation and immunity would be without it.

At the age of fifty-three Metchnikoff turned his attention to the subject of senility. Regarded from a long biological view, man's imperious instinct for life in the later years of existence, notwithstanding obvious breakdowns, must, he considered, be a pathological coincidence. How, otherwise, was the fear of death, a general and inevitable occurrence, to be explained? Metchnikoff imagined that this lack of harmony exists because senility is premature and partial and arrives before the natural instinct for death has had time to develop.

If this supposition were correct, the greatest of life's disharmonies might be remedied, for he believed that it was within the power of science not only to preserve the body from the depredations of disease, but also to maintain the equilibrium of the tissues. In such a case happiness and contentment should be the lot of man for a period far exceeding the usually allotted span. Upon such ideal physiological existence or "orthobiosis" a quiet satiety with living should, he supposed, ultimately supervene and death be welcomed as sleep at the end of a long day.

The consideration of the changes in the tissues in old age led Metchnikoff to the conclusion that, apart from the damage done by diseases such as syphilis, tuberculosis, and other chronic infections, the principal cause of premature degeneration of the important cell elements was a prolonged intoxication by the products of the activities of the innumerable bacteria which inhabit the large intestine. For this hypothesis he obtained anatomical and experimental support.

The former he tersely summarised by the phrase, "the longer the large intestine, the shorter the life," an aphorism which is to some extent responsible for the depredations of some of our famous surgeons.

Having arrived at the conviction that unlicensed bacterial activity in the colon was harmful, Metchnikoff essayed to control it by implanting into the alimentary canal a special microbe which produced much lactic acid from carbohydrates, and was itself

capable of surviving in high concentration of this acid. To this end he recommended, and himself practised, the imbibition of large quantities of soured milk.

Metchnikoff's preoccupation with the disadvantages of senility have been misunderstood and misinterpreted. Although his attention was becoming unpleasantly directed in his own person to the effects of a life of intense activity and mental excitement, coupled with serious cardiac mischief, it is not to be ascribed to the morbid introspection of an invalid. Old age is a legitimate subject for scientific inquiry. It is not unnatural, but unfortunate, that nobody becomes sufficiently interested in the problems of senility until their own age well-nigh precludes the possibility of a successful enterprise. It was approached by Metchnikoff with ideas based on broad biological principles, and most of his late work was really concerned to find justification for them.

Elie Metchnikoff's enthusiasm for his theory of orthobiosis was maintained actually until the end of his life, and the last chapter of the biography contains many records of his mental attitude on contemplating death at short range. He was anxious that these should be recorded as so few with the capacity to analyse their mental processes retain their intellectual powers until the end of life.

His wishes have been piously complied with, and his observations, when confronted with impending dissolution, are faithfully recorded as his final contribution to his theory of the development of the death instinct.

The book is more than an account of the interesting discoveries of Elie Metchnikoff and their far-reaching importance in natural history; it is a human document, an account of the mental adventure of a striking personality, with contemporary science as a setting, told with a *naïveté* reminiscent of Marie Bashkirtseff.

The translation is excellent, and little if any of the charm of the original French is lost. The biography contains as frontispiece a characteristic picture of Metchnikoff in his laboratory, and concludes with a useful bibliography of all his published writings.

Electrical Measurements.

Absolute Measurements in Electricity and Magnetism. By Prof. A. Gray. Second edition, rewritten and enlarged. Pp. xix+837. (London: Macmillan and Co., Ltd., 1921.) 42*s.* net.

ALL physicists are familiar with the first edition of this important work, which, completed in 1893, has long been regarded and used as a standard treatise on electrical measurements. In introducing the second edition Prof. Gray refers at the outset to a certain lack of interest shown by physicists at the present time in the theory and practice of absolute measurements, and it is undoubtedly the case that, in our universities at any rate, the subject receives less attention than was formerly devoted to it. The principal reason for this change may be traced to the nature of such work as the experimental determination of absolute electrical units, and the accurate comparison of secondary standards with them, and also to the great importance which work of this kind possesses. Few, if any, of our university laboratories are sufficiently well equipped for the prosecution of researches in which the construction of apparatus and the carrying out of measurements of the highest precision are involved; and so necessary is this work recognised to be that special laboratories, such as the National Physical Laboratory in this country, and the Bureau of Standards at Washington, have been established, at which it can be more effectively organised and carried out, and at which the research worker in any of the universities may have his measuring instruments accurately standardised. Thus the apparent decline of general interest among physicists in methods of absolute measurement is not due to any diminution in the importance of the subject, but to the fact that the practice of these methods is now more concentrated in institutions specially equipped for the purpose.

A second reason for the change may be found, as suggested by Prof. Gray, in the fact that new and fascinating subjects of study, mainly consequent upon the discovery of the X-rays and radio-activity, have arisen which have been taken up with enthusiasm in our universities, and have to some extent diverted attention from absolute measurements of the classical kind. While it is of the greatest importance that research into the problems of modern physics should be pursued as vigorously as possible, it is no less important to the future of the science that the endeavour to attain greater accuracy in our standards and methods of measurement should not be relaxed. It may well be that the future trend of physical theories will be largely influenced by the degree of accuracy with which some of the important constants can be determined.

The new edition of Prof. Gray's book will be welcomed as a full and clear statement of the present position regarding accurate electrical measurements. There is probably no other book which contains so full an account of the classical experiments for the determination of electrical units and constants, and the many detailed abstracts of original memoirs give the book a special value as a work of reference.

The principal changes found in the new edition

relate to the calculation of the constants of coils, and the theory of absolute electro-dynamometers and current balances, a domain of the subject to which Prof. Gray has himself so largely contributed. His well-known calculation of the mutual inductance of two single layer coils the axes of which intersect at any angle has led to the realisation of an absolute electro-dynamometer, constructed at the Bureau of Standards, the constant of which can be calculated to a high degree of accuracy. It was shown by Prof. Gray that if the coils of the instrument are concentric and have lengths $\sqrt{3}$ times their radii, all the terms between the first and the seventh vanish in the zonal harmonic series for the mutual inductance and the couple between them, and the remaining terms amount to only a very small correction if the dimensions of the inner coil are small in comparison with those of the outer. Consequently the couple is given very accurately by the first term alone of the series—that is, it can be calculated on the assumption that the inner coil is suspended in a perfectly uniform field equal to the field at the centre of the fixed coil.

It is shown how the values of the mutual inductance of two coaxial single-layer coils (including the important case of a helix and a coaxial circle), the self-inductance of a single-layer coil, and the mutual attraction of two coaxial coils, such as those of a current balance, can also be deduced from the general formula. Many other cases are worked out in the chapter on the calculation of inductances, which is much extended in the new edition, and the description and illustrations of the current balances of the National Physical Laboratory and the Bureau of Standards, and the electro-dynamometer of the latter institution, form a valuable feature of the book.

Other portions of the book which are much expanded are those dealing with magnetometry, measurements in alternating current circuits, the distribution of alternating currents in cylindrical conductors, the comparison of resistances, and the absolute measurement of resistance. The recommendations of the International Conference on Electrical Units held in London in 1908, embodying the definitions of the international ohm, ampere, and volt, and the specification of the Weston normal cell, are given in appendices.

Much that was in the old edition has of necessity been omitted from the new; the omitted portions, however, mainly of a theoretical nature, are not directly connected with methods of measurement, and have been fully treated in Prof. Gray's "Treatise on Magnetism and Electricity." The result is a more complete and a better arranged account of methods of electrical measurement and the calculations connected therewith.

In its new form the book is in one volume, and the larger page, the absence of small type, and the numbered sections will make the book more acceptable to the reader. Typographical errors are remarkably few for a work of this size, and in the few cases where results are stated erroneously (as, for instance, the expression for the capacity of a condenser on p. 749) the reader will find no difficulty in supplying the correction.

Of the great value of the book there can be no question, and it may be confidently anticipated that the new edition will be appreciated as highly as was its predecessor.

E. T. J.

The Art of Prehistoric Man.

Prehistory: A Study of Early Cultures in Europe and the Mediterranean Basin. By M. C. Burkitt. Pp. xx + 438. (Cambridge: At the University Press, 1921.) 35*s*. net.

DURING the last two decades great progress has been made in our knowledge of prehistoric man, especially by discoveries in the caves of France and Spain. Most of the results are published in technical memoirs in serials not easily accessible, and it is difficult to follow them without much previous study and extensive reading. Mr. Burkitt has therefore done good service by the preparation of his volume on "Prehistory," which summarises the whole subject and enables both the student and the general reader to appreciate its present position. He himself has taken an active part in much of the research, in association with the Abbés H. Breuil and H. Obermaier; he thus writes from personal knowledge, and adds sufficient details of some of the most interesting localities to make his text-book a useful guide for those who wish to visit them.

Other English books, especially those of Lyell and Boyd Dawkins, have already given a good general account of the discoveries of early man in the caves of this country, so that Mr. Burkitt has done well in devoting attention chiefly to France and Spain. His "outline of the history of the subject," however, fails to give due credit to the English pioneers, whose systematic work in Brixham Cave, Kent's Hole, and Wookey Hole is not even mentioned. MacEnery and Pengelly are overlooked, and Mello's discovery of the drawing of a horse's head on a piece of bone from the Cresswell caves is wrongly described, thus throwing doubt on its authenticity. On p. 76 bone is said to have been "first utilised in Upper Mousterian times," and when this statement, based on French and Spanish experience, is contradicted on p. 89 by a casual reference to the English discovery of a large bone

implement with early Palæolithic flint implements at Piltdown, the latter is briefly dismissed as "possibly the only exception." England has indeed played a prominent pioneer part in unravelling the problems of prehistoric man, and deserves full acknowledgment.

Mr. Burkitt begins with an excellent concise account of man's relation to the glacial period in western Europe, and shows how far the successive races may be correlated with the mild intervals in this period which are marked by the retreat of the glaciers in the Alps and Pyrenees. He also refers to Baron de Geer's counting of the annual layers of sediment which the ice of the last glacial episode in Scandinavia deposited in the sea during its retreat northwards. From this it is inferred that man cannot have reached southern Scandinavia until it was uncovered twelve thousand years ago. The latest phases farther south in Europe must therefore have been somewhat earlier. How long before the glacial period man first appeared here remains uncertain, but both the Abbé Breuil and Mr. Burkitt are agreed that Mr. Reid Moir's discoveries of worked flints in the Red Crag prove his presence in the Upper Pliocene.

FIG. 1.—Incised drawings rom caves in Dordogne and Cantabria. A. A feline, a bear, and a mammoth engraved on the wall of the cave of Combarelles, Dordogne. B. Head of a deer engraved on the wall of the cave of Castillo, Cantabria, with a similar engraving on a piece of bone from the same cave. C. A hog-maned horse engraved on the wall of the cave of La Pasiega Cantabria. From "Prehistory: A Study of Early Cultures in Europe and the Mediterranean Basin."

Most of the volume is devoted to flint and bone implements and art, and Mr. Burkitt traces the successive developments in a more exhaustive manner than has hitherto been attempted. He classifies the flints, and not only records the order of their succession, but also describes exactly several places of discovery which prove their relative age. He shows how bone harpoons may be treated as fossils, and points out the minute differences which mark the successive periods to which they belong. He also describes palimpsests among the cave-pictures which exhibit the superposition of different styles of art. He is thus prepared to determine the relative age of almost any discovery of prehistoric human handiwork. On the whole the school of "prehistorians" to which he belongs is probably right, but it makes no allowance for sporadic outbursts of genius.

The study of the cave-pictures is especially fascinating, and Mr. Burkitt treats it in great detail. Besides the incised figures on the rock, there are paintings in ochre, oxide of manganese, carbon, and kaolin, all mixed with fat. Those of Palæolithic age are isolated drawings, not grouped in scenes, and the majority are in comparatively inaccessible parts of the caves rather than in ordinary living chambers. They were therefore probably not designed for ornament, but in connection with some ideas of sympathetic magic. "No doubt the wonderful naturalistic animals, sometimes

portrayed with the arrows of a hunter in their sides, formed part of a ritual, and were meant to ensure a successful hunt." The incised sketches on bones found in the earth of the floor of the caves were probably in some cases the preliminary studies for the work on the walls and roof.

The volume is illustrated by forty-seven plates, of which we reproduce one (Fig. 1) showing a selection of incised drawings from the caves of Dordogne and Cantabria. All these plates are well described, but they would have proved more useful if they had been referred to in the text. In this and other respects, indeed, the editing of the volume leaves much to be desired, but the work is a unique addition to the literature of prehistoric archæology, and cannot fail soon to reach a second edition, which will afford an opportunity for some useful revision. A. S. W.

The Science of Ancient Greece.

The Legacy of Greece. Edited by R. W. Livingstone. Pp. xii+424. (Oxford: Clarendon Press, 1921.) 7*s.* 6*d.* net.

THIS book redresses in a remarkable way the injustice done to Ancient Greece in most popular works on the subject. Reference to any short history now in use, such as Bury's, or even to such a fine work as "Hellenica" of the last generation, will show that the author finds "the legacy of Greece" in the city-founding activities of the Greeks, and, above all, in the internecine conflicts of the cities in their prime, with some short reference to the Periclean ideal and the philosophic differences of Plato and Aristotle. There is little about literature, less about art, and nothing at all about science. Mr. Livingstone, in planning this volume, has deliberately and rightly set himself to correct this and to put the really substantive achievement of the Greeks in the realm of thought in its due place. The result is that a good third of the book is given to science, and if we include Prof. Burnet's article on Philosophy, which shows its connection with science, we get a larger proportion still. It is most welcome evidence of a change of mind in the university which stands more than any other among us for Greek studies.

The effect is amazing to those accustomed to the old and mainly political outlook, and it will be very wholesome. We see that in every branch of science, in biology and medicine as much as in mathematics, the Greeks laid the foundations on which mankind has built ever since. Sir T. L. Heath well brings this out in his article on Mathematics and Astronomy, which is a complete review of the Greek work from Thales to Diophantus; while Dr. Singer is equally full on Biology and Medicine. The reader will probably share one impression which was borne in strongly on the present reviewer. The writers who describe the newly admitted branches of the legacy of Greece are so full of their subjects, and so eager to display their richness and wonders, that their essays suffer somewhat in comparison with those which deal more allusively with the more familiar topics. Hence the most readable papers, which leave the clearest impression, are Prof. Burnet's on Philosophy, Mr. Livingstone's on Literature, and Mr. Percy Gardiner's on "The Lamps of Greek Art." These are altogether admirable; the leading features are emphasised, and no attempt is made to be exhaustive.

But the fault—if it be a fault—in the essays on science is entirely in the right direction. We have here for the first time in a compendious form the main steps of the Greek construction in mathematics, astronomy, biology, and medicine, and the book is well worth buying for this part of it alone. A charming essay by Prof. D'Arcy Thompson on the Science of Aristotle adds to the attractiveness of the volume, but somewhat disturbs the balance of Dr. Singer's excellent articles on biology and medicine as a whole.

The supreme merit of the book is that it puts in unmistakable prominence the intellectual quality of the Greek mind in its prime, its desire to know, and its power of arranging the material it acquired in that connected form which we call scientific. This is equally salient on the mathematical and the biological side. Sir T. L. Heath shows us how the Greek philosophers had quite early hit on the fundamental equations in geometry; within the seven hundred years of their flourishing they had founded trigonometry through the necessities of their astronomy, anticipated the integral calculus by their method of exhaustions, and laid the basis of algebra in the first generalised notation of Diophantus. In the sciences of life Aristotle had given the first rational classification of living things and an incomparable mass of faithful and detailed description; while the sound principles of Hippocrates in the fifth century in tracing health and illness to natural causes were far in advance of medical theory and practice until the revival of science a thousand years later. It is by these achievements, more than by any other, that the Greeks still rule us from their tombs, and we are deeply grateful to Mr. Livingstone and his coadjutors for putting them in such a clear light without ignoring the due proportion of political theory, art, and psychological philosophy. The well-chosen illustrations add greatly to the value of the volume. F. S. MARVIN.

Jute and Silk in India.

Imperial Institute. Indian Trade Inquiry: Reports on Jute and Silk. Pp. ix+90. (London: John Murray, 1921.) 5*s*. net.

THESE reports embody the results of the work of special committees, formed, in response to the invitation of the Secretary of State for India to the Imperial Institute Committee, to inquire into the possibilities of further commercial usage of the principal Indian raw materials in the United Kingdom and in other parts of the Empire.

The commercial production of jute is confined to Northern India, including Assam. The fibre is obtained from the inner bark of the stems of two annual plants, *Corchorus capsularis* and *C. olitorius*, members of the family Tiliaceæ, and the crop is raised on small holdings by the Indian ryot. More than 60 per cent. of the total crop is consumed in the Indian jute mills, the remainder being exported to the United Kingdom, various Continental countries, and the United States.

In its recommendations the committee has kept in view two main objects, namely, to make use of our practical monopoly of jute to further the interests of the Empire, and to increase the output, and thereby steady and keep at a moderate level the price of the raw product. It recommends an export duty on raw jute leaving India with a rebate in full to consumers within the Empire, the revenue from the duty to be devoted to the establishment of a scheme for the investigation of problems affecting the production in India of jute and allied fibres. As soon as seed-selection experiments are sufficiently advanced the Government should provide each grower with seed sufficient for the season's crop and adopt means to ensure that none but approved seed is sown. Machinery should be set up to deal with the situation arising from a short crop. The production of Bimli jute (the fibre of *Hibiscus cannabinus*) should be encouraged, and means adopted to improve the condition in which it reaches the market.

The position of India among the silk-producing countries is unduly low; natural advantages are not fully utilised, and, at present, the industry is not able to meet local demands. For many years the mulberry silk industry in India has been steadily declining. The committee recommends the establishment by the Government of India of a central Sericultural Institute, the functions of which should include the training of men to develop sericulture in India, the supply of disease-free "seed" of approved native and foreign races of worms, the testing of new races and the production of hybrid races, and the investigation of silkworm and mulberry diseases. Smaller institutions should be established in all important sericultural districts. The committee considers that the enhanced value of Indian silk that would result from a radical improvement in its quality should render it possible for the Indian product to compete successfully with Japanese and Chinese silks.

Valency and Atomic Structure.

Valenzkräfte und Röntgenspektren: Zwei Aufsätze über das Elektronengebäude des Atoms. By Prof W. Kossel. Pp iv+70. (Berlin: Julius Springer, 1921.) 12 marks.

THE literature on atomic structure has received an interesting addition by the publication of this little work, which consists of two essays, the first being entitled "The Physical Nature of Valency Forces," and the second "The Significance of X-rays in the investigation of Atomic Structure." Berzelius first put forward the theory of the electrical nature of valency forces, but the difficulty of explaining homopolar combination by means of it had led to its being discredited. It has now come to the fore again as the result of our knowledge of the relation between atomic number, the charge on the nucleus of the atom, and the place of the atom in the periodic series, and in its recent developments Kossel has played an important part.

In the first paper, after referring to the various atomic models which have been proposed from time to time, Kossel points out that we can explain many of the chemical properties of the elements if we assume a tendency on the part of the atom to lose or gain electrons, so as to revert to more stable electron configuration. In losing or gaining electrons the atom becomes a charged ion, and without knowing anything further of its structure it is possible to explain the formation of a large number of compounds. The valency forces correspond to an electrostatic field surrounding the ion, such as would arise from a charge placed at the centre of the atom. The molecule as a whole must be electrically neutral, but neutral molecules may have oppositely charged atoms at different points in their structure, and so may attract other neutral molecules with the formation of complex compounds. Kossel makes no attempt to explain the way in which homopolar compounds are formed; he merely indicates the lines along which investigation may be possible. He emphasises the point, however, that the study of organic com-

pounds has led to an excessive importance being attached to valency phenomena in homopolar compounds, whereas a complete theory should cover the very large class of inorganic heteropolar compounds formed by the majority of the elements.

The second essay is a short review of the work which has been done on X-ray spectra and the origin of X-rays, with particular reference to the partitioning of electrons into shells surrounding the nucleus.

The author's style is somewhat involved, and for a reader who is not a good German scholar the argument is sometimes difficult to follow.

Our Bookshelf.

(1) *Abridged Callendar Steam Tables, Centigrade Units.* By Prof. H. L. Callendar. Pp. viii. 1*s.* net.
(2) *Abridged Callendar Steam Tables, Fahrenheit Units.* By Prof. H. L. Callendar. Pp. 8. 1*s.* net.
(3) *Callendar Steam Diagram, Centigrade Units.* 6*d.* net.
(4) *Callendar Steam Diagram, Fahrenheit Units.* 6*d.* net. (London: E. Arnold, n.d.)

THE two sets of abridged tables (1) and (2) will be found to contain all that is required for engineering calculations. Table 1 in each set contains the properties of saturated steam for pressures ranging from 28·98 in. of vacuum up to 535·31 lb. per sq. in. gauge pressure. Table 2 gives the total heat of dry steam (superheated or supersaturated), and table 3 contains the entropy values for dry steam at various degrees of superheat and supersaturation. On the first and last pages will be found notes of the symbols and equations employed. The tables are well arranged and clearly printed, and will be of great service to students and engineers in practice.

(3) The Centigrade steam diagram is also well arranged and has convenient scales. (4) The curves on the Fahrenheit steam diagram are copied from those on the Centigrade diagram; the numerals printed on them are the corresponding Fahrenheit numbers. Hence the scales on the Fahrenheit diagram are not so convenient, and we think it would have been better had this diagram been drawn independently of the Centigrade diagram.

Spot and Arc Welding. By H. A. Hornor. (Griffin's Technological Handbooks.) Pp. vii + 296. (London: Charles Griffin and Co., Ltd., 1920.) 15*s.*

THE application of electric welding processes to heavy steel construction, such as obtains in shipbuilding, forms the main topic of this book. The results of extensive tests conducted during the war in the United States with the object of testing the processes are also given. This work was, unfortunately, discontinued at the time of the armistice, but from the results it was shown that trustworthy electrically welded joints can be made of greater strength than corresponding riveted joints, and that consequently some economy in material can be expected. Special designs for all-welded ships are discussed, and a good deal of interesting information is given on other applications of both spot and arc welding and the training of welders. Small all-welded craft have already been constructed in England, and the author shows that the technical knowledge now available is sufficient for a considerable extension of this method of ship construction.

Handbuch der biologischen Arbeitsmethoden. Edited by Prof. Dr. Emil Abderhalden. Abt. 5, *Methoden zum Studium der Funktionen der einzelnen Organe des tierischen Organismus.* Teil 7, Heft 1, Lieferung 12, *Sinnesorgane.* Pp. 195. (Berlin und Wien: Urban und Schwarzenberg, 1920.) 30 marks.

THE "Handbuch der biologischen Arbeitsmethoden," edited by Prof. Emil Abderhalden, will consist of forty-eight parts, in which chemical, physical, biological, psychological, and many other methods are treated at considerable length. The section under notice, by E. Budde, is devoted to the mathematical theory of audition. The first division of this contains a very full discussion of free and forced small vibrations of a point, followed by systems under non-linear forces, including combination tones. The second division deals with strings and membranes, while the third refers to plane-waves in air. Having thus laid the foundation, the author passes to the detailed treatment of human audition, in which he reviews the interpretations of the phenomena put forward by the chief workers on the subject, but dwells especially on the parts played by the basilar membrane and the endolymph.

Turbines. By A. E. Tompkins. Third edition, entirely revised. Pp. viii + 180. (London: S.P.C.K.; New York: The Macmillan Co., 1921.) 8*s.* net.

THE early part of this book is taken up with historical notes and some explanations of the principles involved in the working of turbines. This is followed by three chapters on water-wheels, turbine pumps, and water turbines. The remainder of the book deals with steam turbines. For the most part the book is descriptive, and the simple language employed, together with the many excellent drawings, will render the volume of interest to the general reader. The author has had considerable experience in the working of turbines, and his treatise on "Marine Engineering" is well known. It is therefore rather surprising to find on p. 21, in reference to a rotating wheel, that "every particle of the wheel also tends to fly away from the axis in a radial direction, due to centrifugal action or force." This statement is somewhat misleading. There are one or two misprints, and the accepted notation for British thermal unit is B.Th.U., not b.t.u.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Antitrades.

THE long series of pilot-balloon ascents made at and near Batavia (lat. 6° 11′ S., long. 106° 50′ E.) during the years 1909–17 has given a fair knowledge of the system of air-currents over West Java up to great heights. The general outcome of this investigation has been communicated to the Royal Academy of Science of Amsterdam.[1] My endeavour to explain that system led to a controversy between Dr. Braak and myself and Prof. van Everdingen.[2] After renewed consideration of the problem I have come to new results which I propose to set out provisionally here.

In the memoir presented to the Amsterdam Academy is inserted a synoptical table containing the mean directions and velocities of the wind for each month and for height-intervals of 1 km. up to a height of 24 km. In it the principal air-currents have been made conspicuous by letter colouring and framing. They are :—

First, the *west monsoon* prevailing during the southern summer in the bottom layers up to 5–6 km.

Above it, up to 10–13 km., blow easterly winds with southern components, which I would call tradelike winds. In the winter season such winds blow in the bottom layers up to 3 km.

Above these tradelike winds blow antitradelike winds, *i.e.* easterly winds with a northern component. Their upper limit reaches to 18 km. from December until March; it goes down to 12 km. in June, and again rises to the maximum height of 21 km. in October. The velocities show two maxima: in February at a height of 15 km. (12 m./sec.) and in August at 14 km. (22 m./sec.): in April they are very weak. Not only is their velocity a maximum, but also the transport of air-mass.

Over the antitradelike current appear again currents of tradelike character; however, from March until September an eastward moving air-mass is embedded in them, reaching heights of 24 km. *in maximo.*[3] Very high balloon flights in March and September revealed the existence of strong (30–40 m./sec.) easterly winds up to 30 km.

Considering these results, three principal questions arise:—(1) Are the tradelike winds real trades? (2) Is the antitradelike current a true deflux from the equator towards the sub-tropics? (3) Whence do the great velocities of the high antitradelike and upper tradelike winds originate?

The currents mostly possess a stationary character, and consequently their directions will be in close agreement with the trend of the isobars in their level. For Java the latter will be conditioned by the neighbourhood of the Australian continent. As in the southern winter over Australia is settled a circular High, we may expect over Java the trend of the isobars to be E.N.E.–W.S.W. and the gradient to be towards the equator. However, by friction with the earth surface the air blows across the isobars and takes an E.S.E.–W.N.W. direction. This means real outflow to the equator; thus the tradelike wind mentioned above is a trade.

In the southern summer over Australia lies a Low, causing the west monsoon, but above this Low the gradient is reversed and a High prevails. This causes in the same manner as mentioned above a tradelike wind. The friction required for it, I presume, is caused by the streaming one over another of the two currents with contrary directions (the west–east below, the east–west above). Thus, I think, the first of the three questions put forward has been answered in the affirmative: the tradelike winds are trades.

As to the second question, we may consider first the southern winter season. In it the gradient Australia–Java is reversed at the level of ±5 km. But does it change too in the other season at 3 km.? Apparently not, because, going upwards, the easterly winds do not then change to westerly ones; they back only from E.S.E. to E.N.E., while the velocity does not vanish. Now, admitting the absence of friction in these layers, and consequently assuming the current to follow the course of the isobars, we come to the conclusion that this course remains mainly the same when going upwards, or the Australian High subsists in these higher layers, though perhaps shifting somewhat to the eastward.

Accepting this, we may ask: Might it be that the antitradelike current flows around the Australian High, bringing about thus the deflux towards the subtropics?

In that case the antitradelike current should be a true antitrade, although of local character. But then we are obliged to admit that a flux towards the equator will also occur at the opposite side of the oval system of the Australian High; only the deflux should surpass it by the mass of air (or part of it) which ascends from the surface in the equatorial belt.

This influx, too, may give us an answer to our third question: What is the cause of the great east–west velocities of antitradelike and upper tradelike winds? Exner[4] points to the fact that ascension of air at the equator is able to increase its east–west velocity only by a fraction, and, therefore, tries to explain the great velocities of high equatorial east winds by shifting of air from higher latitudes towards the equator with preservation of rotational moment. A meridional shift from latitude ±15° causes velocities from 30–40 m./sec.

My result for the antitradelike current over Java is the same as that obtained by Sir Napier Shaw when calculating isobars for the level at 8000 metres.[5] He, too, finds long-stretched Highs, and he speaks of the flowing of air around these Highs, by which the east–west wind velocities of the equator act on the opposite currents of the sub-tropics as by chain-drive pulling.

However, through lack of data Sir Napier Shaw had to calculate his isobars by means of one and the same set of vertical temperature-gradients for the whole hemisphere, which, of course, makes the results somewhat doubtful for the equatorial belt, because there the critical pressure-differences at the 8000-metre level are small only.

For that reason I have sought for another independent way to solve the antitrade problem, and I think I have found it by mapping the average directions of cirrus drift as observed in the equatorial belt.

Cirrus floats there at levels of about 11 km., and

1 Proceedings, April 16, 1918.
2 *Tijdschrift v. h. K. Aardrijkskundig Gen.*, vol. 35, 1918, No. 1, and vol. 36, 1919, No. 4.
3 Owing to a typographical error in the synoptical table the velocities at the levels 18, 19, and 20 km. for June have wrongly been given as 1 m./sec. instead of 10 m./sec.

4 "Dynamische Meteorologie." 1917, p. 182.
5 Rede Lecture. NATURE, July 21, 1921. p. 653. Sir Napier Shaw most kindly provided me recently with a copy of the unpublished *isobaric charts* which he constructed for the northern hemisphere

at that height over Java the antitradelike winds blow from May until October, while during the rest of the year winds with tradelike character prevail.

The mean directions of cirrus drift which were at my disposal (mostly borrowed from H. Hilderbrandson [6]) I plotted separately for winter and summer, and although they are very sparse I made an endeavour to construct lines of flow. The result is incorporated in the accompanying maps (Fig. 1). They should be regarded as a first trial; *e.g.* no attention was given to the density of the lines of flow, only to their direction. For three stations (Hawaii, Ascension, and Congo) only annual means were given, and they have been used for both summer and winter.

Trying to design the lines of flow, it was apparent this could be done only by assuming oblong systems to exist at both sides of the equator, together with a zonal stream winding about the equator. Of these ovals those lying over Central America, Northern Africa, and Southern Asia correspond fairly well with the isobaric Highs found by Sir Napier Shaw at the 8-km. level.

The mean amount of seasonal shifting found above, *i.e.* 10°, fairly agrees with the corresponding shifting of these high-pressure belts at the surface :—

Northern Belt		Southern Belt.	
January ...	32° N.	January ...	37° S.
July	39° N.	July	28° S.
Shift ...	7°	Shift ...	9°

Resuming, it seems probable that in high levels above the equator and winding about it flows a zonal east–west current of stationary character, which is fed by ascending surface-air and locally by air streaming in from higher latitudes, which, moreover, maintains its east–west motion. Also, that from it flows off in other places air to the sub-tropical belts; these currents of deflux bend from an east–west to a west–east direction.

This communication may prove anew that the knowledge of the direction of the cirrus drift in the equatorial belt is important for the investigation of atmospheric circulation between the tropics, but that

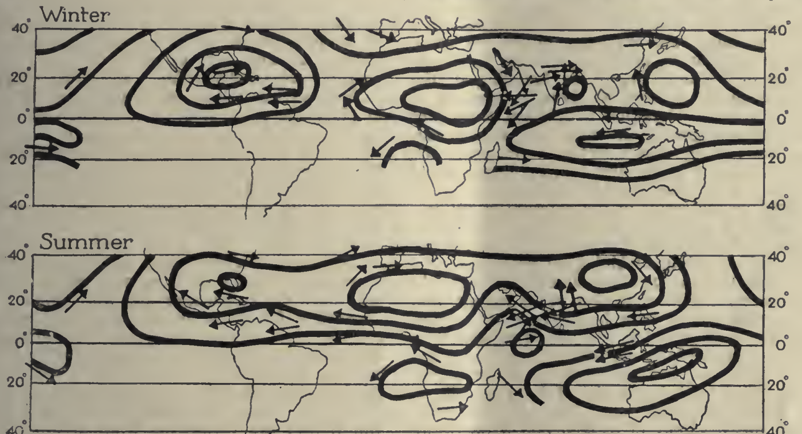

FIG. 1.—Lines of flow of cirrus drift.

Estimating roughly the latitudes of the centres of the current-ovals I find :—

Oval over	Latitude of centre: Winter	Summer	Seasonal shift
Central America ...	20 N.	28 N.	8
Northern Africa ...	8 N.	25 N.	17
Southern Africa ...	?	18 S.	—
Arabian Sea	—	0	—
Bengalese Sea	15 N.	—	—
East Asia	17 N.	30 N.	13
Australia	13 S.	10 S.	3
		Mean ...	10

The mean latitude of the northern ovals is about 20°, that of the southern about 15°. At the surface of the earth pressure is highest in latitudes 35° N. and 30° S.; accordingly, when identifying the current-ovals with pressure Highs, the latter are 15° nearer to the equator at the 11-km. level than at sea-level. This shifting is in agreement with the considerations of Teisserenc de Bort and Exner (*loc. cit.*, p. 177), according to which the high-pressure belts with increasing height move towards the equator.

[6] "Les Bases de la Météorologie dynamique," II. Also Nova Acta R. Soc. Sc. Upsaliensis, ser. 4, vol. 5, No. 1.

the observations at our disposal are few and rather insufficient. For that reason I appeal to those who are in the position to make these observations to supply this need.

To observe in what direction cirrus floats is easy and requires simple means only; moreover, observations are not confined to fixed hours or days. Thus they are particularly adapted to be made by amateurs living in the tropical regions. W. VAN BEMMELEN.

Some Problems in Evolution.

THE controversy between Sir Archdall Reid and the biologists is partly concerned with the meaning of terms and partly with the understanding or misunderstanding of physiological processes. Sir Archdall insists on certain interpretations or definitions of the terms "inherited" and "acquired." These terms were first used by the biologists, and Sir Archdall should not give them meanings of his own different from those which they originally bore. He insists that there are two kinds of variation, but only one kind of character. The word "variation" has been used to mean the small differences always found

between individuals of the same species, and also the larger, more conspicuous departures from the average type or normal character. The former are now called "fluctuations," the latter "mutations." Sir Archdall agrees that a variation may result either (*a*) from germinal or (*b*) from nurtural differences, but he repeats his assertion that all characters are alike with respect to acquiredness and inheritability.

Now I presume that when a variation of germinal origin is inherited it is correctly called a "character." For example, the rose-comb in fowls is a character, and we may suppose that it arose as a variation of germinal origin. We know that it is inherited. But Sir Archdall asserts that when it appears in an individual it is also "acquired" because it was not present in the new-laid egg. Here then he is merely, without any justification, giving a new meaning of his own to the term "acquired," which was applied by biologists to those differences which were not of germinal origin. He insists on substituting in this case the term "acquirement" for the term "development."

On the other hand, if a man rows much he develops first blisters, and then corns, on his hands. According to Sir Archdall, this character is inherited because a son would reproduce the character under the same conditions as the parent produced it—that is, under the stimulus of friction due to the handling of the oar. Here again Sir Archdall is giving a meaning of his own to the term "inherited" different from that which biologists originally intended and understood. Supposing the rowing man's father never had such corns, still, according to Sir Archdall, the corns would be inherited. Biologists would say that the corns were acquired as the result of the external stimulus.

What I wish to point out is that this alteration in the meaning and definition of terms is due to a fundamental misunderstanding of biological processes. Sir Archdall states that a fowl reproduces the comb in response to nurture similar to that of its parent, and the man reproduces the corn in response to nurture similar to that under which his parent would have produced it; therefore both are inherited and both are acquired. What is the resemblance between the two cases? The fowl is nourished by the yolk of the egg before hatching and by its food after hatching; it has a supply of oxygen and temperature within certain limits, and "in response" to these conditions the comb develops. The man is nourished by nutriment before birth, by food after birth, requires oxygen and warmth, *and then his hands are subjected to friction* and the corns develop. It is a manifest absurdity to say that the two cases are of the same kind or analogous. It is easy enough to reduce two different phenomena to the same form of words and then assert that they are of the same kind; it may show ingenuity, but it obscures the truth, and is contrary to the methods of science.

The fallacy of Sir Archdall's argument lies in the words "in response to." After admitting the difference between two kinds of variation, he maintains that the comb, or, taking the more special character, the rose-comb, develops in the offspring in response to similar nurture, *i.e.* the same conditions as in the parent, and that precisely the same may be said of corns produced by rowing. But this is not the truth; it is the exact opposite of the truth. The rose-comb is not a "response" to any of the conditions of the nurture. We may take cocks and hens which are the produce of a cross between rose-comb and single comb, and which all have rose-combs; when we breed from them some of the chicks develop single combs and some develop rose-combs. Which comb-character is the "response" to the similar nurture, parents and offspring having all had the same nurture?

Sir Archdall fails to perceive the difference between a condition or stimulus in the nurture which has a direct relation to a structural feature and conditions which have no such relation. In the case of the corns due to rowing, the increased growth is a definite response to the stimulus of friction. In the nurture of fowls there is no stimulus to which the comb or any comb-character is a response. A character is inherited, not necessarily under the same conditions, but under a great variety of conditions, and vast numbers of different characters are inherited under the same conditions. Consider the various plants in a garden: their characters cannot be said to develop in response to nurture. No stimulus or treatment will produce a purple sweet-pea from a white sweet-pea; apart from variations, the different varieties of plants develop the characters of their parents in the same garden under the same conditions. When a stimulus is found which produces a certain change, then that change is an acquired character.

It is an essential point that the fowl develops in response to nurture, but not the comb-character or any other inherited character. Heat at a certain temperature is a necessary stimulus to the development of the egg, but it is not a stimulus to any particular character. The eggs of all the various breeds with all their remarkable colours and other characters can be incubated at the same temperature. It is a fallacy to place the relation of heat to general development in this case in the same category as the relation of friction to corns in the other. The question is: What determines the character? Friction of the hands produces a particular structural change; heat in incubation has no effect whatever on the characters of the breed to which the eggs belong.

Sir Archdall has stated that the corns due to rowing are inherited, and has treated them as a character. In this case, what becomes of the difference between a character and a variation? We may suppose a family of people who have not practised rowing; one adopts the practice and develops corns. Are these a character or a variation? Is the rose-comb a character or a variation? Sir Archdall has tried to show that the two are characters of the same kind with regard to acquirement and inheritability. But if they are variations, what becomes of the two kinds of variation?

Readers of NATURE are probably as weary of this controversy as I am, but Sir Archdall Reid is doing much harm by leading many who have no special knowledge of heredity and evolution to distrust the work of those who are engaged in research on these subjects. Prof. Bayliss recently stated that it was clear from this correspondence that the actual meaning of the terms used was in dispute. I feel that it is necessary, therefore, to criticise Sir Archdall's statements.

J. T. CUNNINGHAM.

East London College, Mile End, E.,
January 28.

IN his recent letter to NATURE (January 26, p. 104) Sir Archdall Reid restates his belief that "all characters are alike as regards innateness, acquiredness, and inheritability." His difficulties in this matter appear to be largely of his own creation, and they might be dissipated if he paid less attention to words and greater attention to the facts of experimental biology.

Sir Archdall Reid admits that there are "two kinds of variation: (*a*) those which result from germinal, and (*b*) those which result from nurtural, differences." That being the case, it surely follows that there are two kinds of characters; for what is a character but

a difference which has arisen at some time through a variation? We can determine characters only by comparing related organisms and noting their differences. To say that all characters are alike, then, is to say that all variations are alike, which Sir Archdall Reid himself admits is not the case.

Perhaps an experimental instance will make this clearer. Some years ago a fasciated specimen of an Œnothera was sent to me. The plant was in seed; the stem was about 2 in. wide at the widest part and as flat as a ribbon. It was, of course, impossible to say with certainty, from inspection, whether this character would be inherited or not, although the probabilities were somewhat against it. I sowed the seeds, large numbers of them, and they all gave rise to perfectly normal plants with round stems. The character was therefore non-inherited in this particular case. It is, of course, well known that fasciations may be produced by excessive nutrition, and that the peculiarity is then, as a rule at least, not inherited.

But there are other instances in which this character *is* inherited. For example, in the common coxcomb of gardens, *Celosia cristata*, fasciation is one of the specific characters, distinguishing it from such species as *Celosia plumosa*, in which the stems do not fasciate under ordinary conditions of cultivation. I have often grown these two species in quantity side by side in the greenhouse, and compared the extreme fasciation of *C. cristata* with the ordinary branched character of the other species. It should be mentioned, however, that *C. plumosa* does sometimes show slight fasciation at the tips of the branches, and this can be exaggerated by growing the plants under conditions of very high temperature and moisture. But it never approaches the degree of fasciation found constantly as a specific (and therefore inherited) character in *C. cristata*.

The same character, fasciation, is therefore clearly inherited in *C. cristata*, but it was not inherited in the particular instance in Œnothera which I tested. It is also clear that the fasciated Celosia must have originated at some time as a variation from plants with normal stems. Innumerable similar instances will be known to experimental biologists, and it is such cases which they have in mind when they speak of characters as of two kinds, inherited and non-inherited. When a particular new character appears as the result of a variation no one can predict with certainty whether it will be inherited or not until the organism which shows it is tested. But, of course, probabilities may be stated by comparison with similar characters the hereditary behaviour of which is already known. In the face of such experimental facts, which are well known to all geneticists, it is futile to state that all characters are equally acquired and equally inherited.

When Sir Archdall Reid implies that combs and corns are equally inherited he forgets a whole class of experimental facts such as those above cited. One must refuse to consider corns as inherited, because there always remains the possibility that a case may arise where, through a germinal change, they *are* inherited without any special stimulus to produce them. The inherited condition known as keratosis is, indeed, an epidermal thickening of similar character. It seems clear that moles are not usually inherited, but if the writer in Nature is correct (see Nature, January 19, p. 78), then there may be instances in which even a mole is inherited in the legitimate sense in which the term "inheritance" is customarily used by biologists.

R. Ruggles Gates.

King's College, University of London,
January 27.

Sir Archdall Reid's letter in Nature of January 26 will render considerable service if it induces students of evolutionary phenomena accurately and precisely to define their terms.

If one may, at the beginning, set forth two general statements, the ground will be cleared for a discussion of Sir Archdall Reid's points:—

(1) Genes or factors are inherited, characters are not.

(2) A gene conditions the appearance in the organism of a character or group of characters.

(3) The effect produced by a gene in the organism depends on the environmental conditions which prevail during the life-history of the organism and on the other genes which the organism possesses.

To show that characters are not inherited, the example of "abnormal abdomen" in Drosophila may be cited.

The gene for "abnormal abdomen" causes the condition in moist cultures only. In dry cultures the flies hatch out normal in appearance.

The statement that rose comb and single comb are not more inheritable than corns on oarsmen's hands is obviously correct. Any capacity for reacting to a stimulus may be considered as being represented in the chromosomes by a gene or genes. In this case we may assume that the capacity for responding to the frictional stimulus of the oar by forming a mass of proliferated tissue on the palms of the hands is inherited.

Certain other points raised by Sir Archdall Reid may be dealt with briefly:

(1) The impure dominant does not inherit any trait. It inherits the recessive gene from one parent which may or may not interact with environment and with other genes to produce an effect. The terms "dominant" and "recessive" are purely arbitrary, and used only for convenience.

(2) The pure extracted recessive inherits a recessive gene from one parent and a similar recessive gene from the other. The germ-cells of an impure dominant carry either the dominant or the recessive gene.

(3) The ancestral condition obtained in some pigeon crosses is due to the interaction of the two sets of genes contributed by the two parents.

The interaction of genes may be illustrated by an example from the cow-pea. A red cow-pea crossed with a white may give a black in the first hybrid generation. White possesses a gene for black which is without effect except in the presence of the gene for red present in the red parent. At least eight different genes in the cow-pea are known to depend for their expression on a single colour-conditioning gene.

S. C. Harland.

[Sir Archdall Reid began this correspondence with a letter in Nature of November 25, 1920; and we have now invited him to close it.—Editor.]

The Radiant Spectrum.

Dr. Hartridge's objections to my explanation of this phenomenon (Nature, September 1, p. 12, and December 8, 1921, p. 467) seem to be based on an imperfect appreciation of Brewster's observations on the subject. Brewster brings out two facts clearly in his paper: First, when a very small and intense source of white light is viewed directly by the eye it appears surrounded by a system of radiating streamers which appear to diverge directly from it; secondly, when a prism of small dispersive power is interposed in front of the eye the streamers are deviated and now appear to diverge from a point lying beyond the violet end of the spectrum into

which the source itself is drawn out. It is clearly illogical to suggest, as Dr. Hartridge does, that the prism is responsible for the radiant phenomenon in view of the fact that, in its essential features, the effect is observed even before the introduction of the prism.

Using a sufficiently intense source of light and a prism of small angle with optically good and clean faces, and making the observations in a dark room, it should be easy for anyone to satisfy himself by simple tests of the kind referred to by Dr. Hartridge that he is in error, and that Brewster's phenomenon really arises from the scattering of light in the eye, the prism merely acting as a dispersive apparatus modifying the colour and disposition of the streamers in the halo surrounding the source. Judging from the statements made in his letter, Dr. Hartridge would appear to have been particularly unfortunate in his choice of experimental conditions. Any noticeable imperfection in the optical surfaces of the prism would, of course, give rise to scattering, masking the true phenomenon due to the eye itself. This is indeed clearly suggested in Brewster's own paper.

A further and absolutely crucial test is also available. In my paper on the scattering of light in the refractive media of the eye (*Phil. Mag.*, November, 1919, p. 568), I have described the character of the diffraction-halo arising from this cause in considerable detail. With a source of white light the halo shows a radiating fibrous structure and clearly marked alternations of colour and intensity in its outer parts. A monochromatic source, on the other hand, exhibits a halo with a granular structure and a succession of bright and dark rings. These features are explained in my paper as due to the diffraction of light by corpuscles of more or less uniform size included within the structure of the eye. On this view we should expect one half of the first diffraction ring outside the central portion of the halo to be partially achromatised on the introduction of the prism and to appear as a detached semi-circular arc lying beyond the violet end of the spectrum and the displaced position of the achromatic centre. No mere imperfections or irregularities in optical surfaces could, on the other hand, give rise to such a phenomenon. Actual trial confirms the expectation from theory and puts its correctness on an unassailable basis.

C. V. RAMAN.

210 Bowbazaar Street, Calcutta, January 4.

The Naming of the Minor Planet No. 907, Barnardiana.

IN NATURE for September 8 last (vol. 108, p. 69), at the end of "Our Astronomical Column," attention is directed to the naming by Dr. Max Wolf of two of his asteroids in *Astronomische Nachrichten*, No. 5116. They are No. 834, Burnhamia, and No. 907, Barnardiana. In commenting on these asteroids NATURE infers that they were named after two American astronomers. While it is true that Prof. Burnham's memory is thus honoured, Barnardiana was not named after me, but in memory of Mrs. Rhoda Calvert Barnard, who died on May 25, 1921. This is evident from the following quotation from a letter to me by Dr. Wolf on the subject:—

"Wenn ich den Vornamen Ihrer Gemahlin gekannt hätte, und—vorausgesetzt, dass er nicht schon verwendet worden ist—würde ich ihn einem meiner Planeten zur Erinnerung an Ihre liebe Frau beigegeben haben. Da das nicht ging, so taufe ich den Planeten 907 1918 EU, auf den Namen: Barnardiana."

For some reason No. 5116 of the *Astronomische Nachrichten* containing these names has only very recently reached the Yerkes Observatory. I was unaware until then that it did not distinctly state the planet was named after Mrs. Barnard. Though not actively engaged in astronomical work, in her long life in astronomy she had endeared herself to the many astronomical people she had met by her thoughtful and unselfish interest in them and in their work. Hers was a life of love and sympathy. I am grateful to Dr. Wolf for thus perpetuating her memory.

E. E. BARNARD.

Yerkes Observatory, University of Chicago,

The Resonance Theory of Hearing.

DR. HARTRIDGE imputes to me great absurdities which, either in irony or by an excess of courtesy, he terms "slight errors" (NATURE, January 19, p. 76). Under (1) he takes my plain words, the result "must always be of the same nature," to mean that the result must always be the same! Of course, the harmonic analysis of his oboe and flute combination will not give the same result as in the case of violin and cornet, but in both cases the result will be of the same nature, in that there will be only one fundamental tone. If the data supplied to the sensorium from the cochlea are simply the result of an harmonic analysis, the two notes must appear to the ear inseparably blended in one note. I have not left binaural audition out of consideration. The ability to distinguish two concurrent notes of the same pitch and different quality seems unaffected by both sources being equidistant from either ear.

Under (2) Dr. Hartridge should know as well as I know that the *pitch* of a note depends solely upon the period of its fundamental tone. The example which I proposed eliminates the possibility of beats, the two notes being in perfect physical unison. And, further, since the note made by the teeth is generated by the other note, it cannot be heard except in the combination. Its perception is, therefore, a cognition, not a recognition. *At any instant* during the production of the two notes (which may be sustained for twenty seconds easily) it is possible to turn the attention to the note made by the teeth and to hear that its pitch is that of the hummed note. *At no instant* could the resonators which Dr. Hartridge, outstripping Sir Arthur Keith, "finds" in the cochlea furnish the data for anything but a change in the quality and intensity of the hummed note. This objection remains untouched by Dr. Hartridge's animadversions. It goes to the root of the matter, and cannot "fall to the ground" as a superstructure may.

W. PERRETT.

Aurora Borealis of January 30.

HAPPENING to look out at 11.30 last night I perceived a strong auroral glow extending from N. by E. through N. to W. The light was quite bright, and on going into the garden I noticed that my body cast a shadow and that I could read the headlines of the *Times* quite readily. There were no streamers, but several luminous patches, especially due N., where a blunted cone of greenish light rose vertically up from the horizon to a height of 10°.

The sky was partially, and later almost totally, covered by thin clouds, which drifted up from S. under the influence of light airs. The atmosphere was misty and the temperature decidedly warm.

Some Statistics of Evolution and Geographical Distribution in Plants and Animals, and their Significance.

By Dr. J. C. Willis, F.R.S., and G. Udny Yule, C.B.E., F.R.S.

In a paper read at the Linnean Society under the above title on February 2, the statistical methods long employed in "Age and Area" were pushed to their final conclusion. Age and area (review in *Ann. of Bot.*, October, 1921, p. 493) is the name given to a principle gradually discovered in many years of work upon the flora of Ceylon, which, in brief, affirms that if one take groups of not less than ten allied species and compare them with similar groups allied to the first, the relative total areas occupied in a given country, or in the world, will be more or less proportional (whether directly or not we do not yet know) to their relative total ages, within that country or absolutely, as the case may be. The longer a group has existed the more area will it occupy. Tens are compared in order to eliminate chance differences as much as possible, and allied groups to avoid as far as may be the complications introduced by different ecological habit, etc. Herbs, for example, probably spread much more rapidly than trees, but both will obey Age and Area. It is of course obvious that age of itself cannot effect dispersal, but inasmuch as predictions as to distribution of species, occurrence of endemics, etc., can be successfully made upon the basis of age *alone*, it is clear that the average rate of spreading of a given species, and still more of a group of allied species, is very uniform, and therefore affords a measure of age. The result of the work is to show that in general the species (and genera) of smallest areas are the youngest, and are descended from the more widespread species that usually occur beside them.

To Age and Area must be added, as will be shown in a forthcoming book, the twin principle of "Size and Space," which affirms that within any circle of affinity the total of areas occupied by any group of ten genera will go with the total number of species, being large when that is large. The monotypic genera, like the species of small area, must in general be young beginners, and descended from larger genera. Putting these two principles together, it is clear that age, area (or space), and size go together, and as age (representing the resultant of the active factors) is the only working factor of the three, whatever phenomena are shown by size should be similar to those shown by space. But size of genera represents evolution, and area or space represents geographical distribution. These two phenomena should therefore show similar expressions.

But the characteristic feature of geographical distribution, as indicated in all the work upon Age and Area, is that species, whether of endemic or of non-endemic genera, are arranged, as regards their areas of dispersal, in "hollow curves."[1] They show (*cf.* last curve of Fig. 1) many on the smallest area (here one island), fewer on the area next larger (here two islands), and a tail of a few on areas larger again. This type of distribution is practically universal; if one take, for example, a large and widely distributed genus like Cyrtandra, one finds 145 species on small areas, twenty on areas of moderate size, and two on very large areas. If one take the Hawaiian Islands alone, one finds that this genus has twenty-four on single islands, two on two, two on three, and one on four.

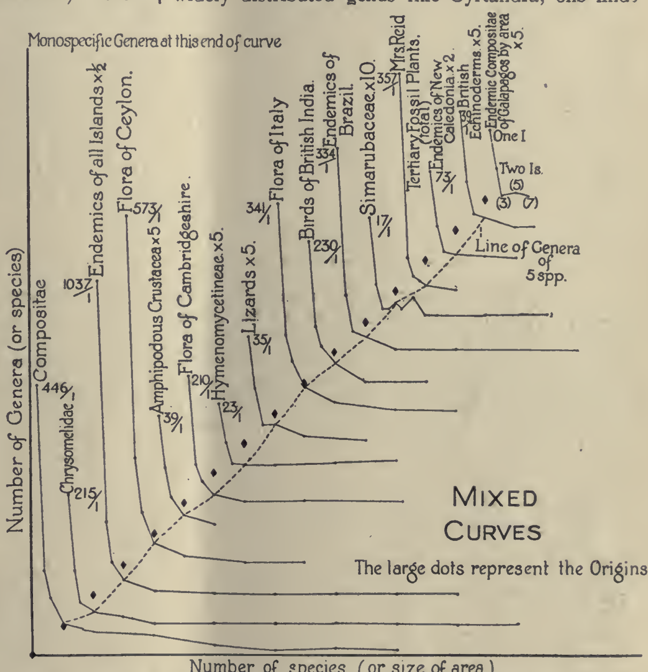

Fig. 1.—Mixed hollow curves. The numbers (thus 446/1) at the beginning of each are the numbers of monotypes.

Now evolution, as expressed in the sizes of genera, shows exactly similar phenomena, and if one group together genera that are associated in any way, systematically, ecologically, or in a given local flora, one gets just the same type of hollow curve, as

[1] By a hollow curve is meant the curve obtained by plotting graphically a series of numbers of which the first is much the largest, while there is a considerable drop to the second and again to the third, and then a gradual falling off to the end. The first two make up about half the total. For instance, a hollow curve will be obtained by plotting 40/1 (40 of one species), 15/2, 8/3, 6/4, 5/5, 3/10, 2/20, 1/30. Many examples are given in Fig. 1.

Fig. 1 shows. It begins with many genera of one species, fewer (but still many) of two, and tapers away in a tail to the larger genera, the tail being longer the larger the family or area dealt with (the tails in the figure are usually very incomplete: Compositæ, for example, run to 1450). A number of

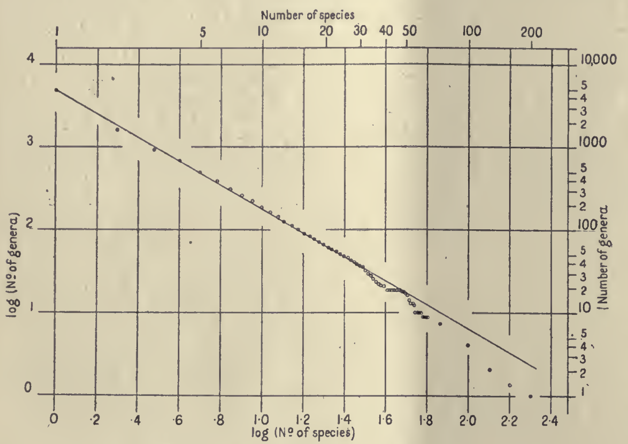

FIG. 2.—Log. curve for all flowering plants.

curves are plotted together in Fig. 1, and show that this type of curve holds not only for all the genera of the world, but also for all the individual families both of plants and animals, for endemic and for non-endemic genera, for local floras and faunas (as may be verified in an hour), and even for very local floras, such as that of Cambridgeshire; it holds even for Wicken Fen and other strictly local associations of plants. It obtains, too, as Mrs. Reid showed in a note read the same evening, for all the deposits of Tertiary fossils examined. For the first three numbers it shows very clearly, but as the numbers become smaller they tend to be irregular, though always diminishing towards the end. If one take only the tens, twenties, etc., one obtains a practically smooth curve.

But now, if species of very limited area and genera of one species (which also have usually small areas) are, with comparatively few exceptions, the young beginners in the race of life, and are descended in general from the species of wider dispersal and the larger genera, and if the number of species in a genus is, broadly speaking, a measure of its age, the idea at once suggests itself that a given stock may be regarded as "throwing" generic variations much as it throws offspring, so that the number of genera descended from one prime ancestor may be expected to increase in geometric ratio or according to the law of compound interest. The number of species descended from one ancestor might be expected to follow the same form of law with a more rapid rate of growth. On such a very rough conception it is found that the form of frequency distribution for sizes of genera should follow the rule that the logarithm of the number of genera plotted to the logarithm of the number of species gives a straight line. Fig. 2 shows the results of this method of plotting for all the flowering plants of the world. The dots give the data, graduated; some process of graduation had to be used, as the statistics were based on the figures given in the "Dictionary of the Flowering Plants and Ferns," which are rounded off in doubtful cases to the nearest 5 or 10 (or greater number in the large genera). It will be seen that, up to genera of some thirty or forty species, there is an excellent fit to a straight line, though there is a marked deficiency of the larger genera—a point on which further investigation is required. Single families show precisely the same rule, the lines not differing very greatly in slope: Fig. 3 gives an illustration of the chart for the Rubiaceæ. Nor is the law one confined to plant life, as is shown by Fig. 4, for the family of Chrysomelidæ amongst the beetles.

It follows from the conception stated that the

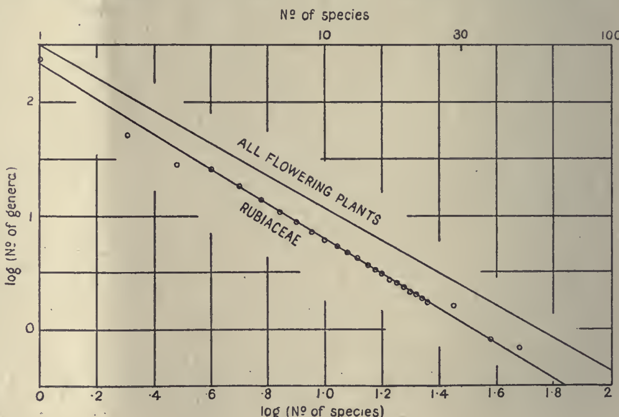

FIG. 3.—Log. curve for Rubiaceæ.

excess of the slope of the line over unity should measure the ratio of the rate of increase of genera to that of species. The slope should always, therefore, lie between the limits 1 and 2, for a slope of less than unity would have no meaning, and a slope exceeding 2 would imply that generic variations

were more frequent than specific variations. Hitherto no exception has been found to the required rule. One group of fungi tested (Hymenomycetineæ) gave a line with a slope very little exceeding unity (1·08), but the figures found for flowering plants lie between the narrow limits 1·38 and 1·64, with an average of about 1·43. Snakes and lizards both give a figure very near 1·50, and the Chrysomelidæ about 1·37.

The development of a more complete theory may in some degree modify conceptions and interpretations, but the results so far obtained suggest that the basic principle put forward is correct.

Inasmuch as all families, both of plants and animals, show the same type of curve, whether graphic or logarithmic, it would appear that in general the manner in which evolution has unfolded itself has been relatively little affected by the various vital and other factors, these only causing deviations this way and that from the dominant plan. And since, assuming that genera "throw" other genera and species, it was predicted that the logarithmic curves would be straight lines, and it was then discovered that they actually were so, it is probable that the assumption was correct. But if this be so, then not only must evolution have been by mutation, but it must also have been, as one of us has contended for many years, by mutations that were at times of rank sufficient to give rise to Linnean species, genera, or even families. Not only so, but evolution must have proceeded on the lines of Guppy's theory of differentiation, the larger genera, and the species of larger area, being the parents of the smaller: *i.e.* it must have proceeded on the whole in the reverse direction to that postulated by the Darwinian theory, as one of us has long maintained.

Finally, it is clear that geographical distribution has been largely mechanical, the general effect of the many factors that are operative being to cause species to spread at a fairly regular speed (differing for each), so that spread forms a measure of age.

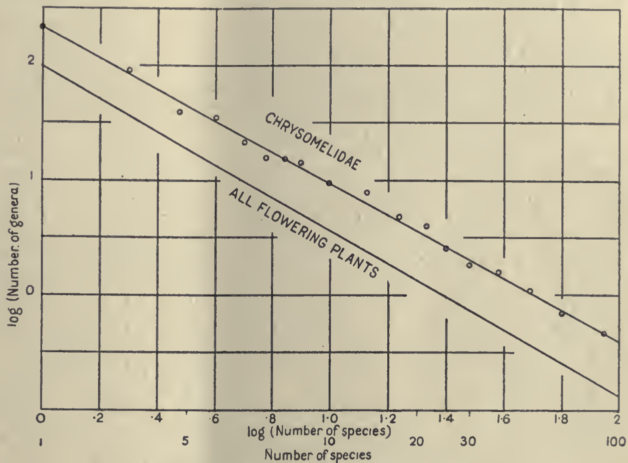

FIG. 4.—Log. curve for chrysomelid beetles.

Space does not permit of detailed argument, which must be left for forthcoming books; but a couple of hours' work at statistics of genera (by sizes) will suffice to make clear the general position taken up.

Some Problems of Long-distance Radio-telegraphy.[1]

By DR. J. A. FLEMING, F.R.S.

II.

ANOTHER cause operating to effect a separation of the positively and negatively charged dust is found in the viscosity of the atmosphere. Roughly speaking, the viscosity of a gas is that quality of it in virtue of which fine particles experience a resistance in moving through it. Maxwell showed long ago that the viscosity of a gas is independent of the pressure over wide limits. Crookes continued these researches and demonstrated that between atmospheric pressure and a pressure of about one ten-thousandth of an atmosphere the viscosity remains constant, but that when the pressure falls below this last figure the viscosity very rapidly decreases to zero. Again, both Maxwell and Crookes found that the viscosity of hydrogen is about half that of oxygen or nitrogen. The viscosity of air at 760 mm. is 0·00018 C.G.S. units.

Sir George Stokes proved that if a small sphere of diameter d and density σ is falling through a gas of density ρ and viscosity μ under the action of gravity it will attain a final velocity v such that

$$v=\frac{1}{18}\frac{d^2g}{\mu}(\sigma-\rho),$$

where g is the acceleration of gravity. This explains the extremely slow rate of fall of water particles constituting clouds, and also the very slow settlement of fine dust particles through air.

The positively-charged solar dust particles are probably larger than the negatively-charged particles, as the latter consist of electrons having condensed round them molecules of gases, probably hydrogen and helium, gathered from the solar chromosphere. Accordingly the negative ions will be brought to rest before the positively-charged particles and gas viscosity will assist the separation.

But Stokes's expressions apply to smooth spheres and not to irregularly shaped particles. Also, if the diameter of the particle is much less than the mean free path of a gas molecule, the expression

[1] Continued from p. 143.

for the frictional resistance, $3\pi d\mu v$, must be divided by $1+2aL/d$ where L is the mean free path of a gas molecule and a is a constant depending on the nature of the particle and its form.

If, then, particles of dust enter the highly rarefied upper hydrogen levels of the atmosphere, they will experience very little retardation until they reach that level (about 100 km.) at which viscosity begins to increase rapidly to its normal or full value, but then they will be very quickly brought to rest even in spite of their high initial velocity.

Hence none of this dust will penetrate below a certain level in the atmosphere, probably from 60 to 80 km. It will be stopped and held by air viscosity. The moment its velocity falls off the forces tending to separate the oppositely electrified particles will also decrease, and the oppositely charged particles may then neutralise each other. The result will be, as I think, to give the highly conductive layer in the earth's atmosphere a tolerably well-defined under-surface determined by the very rapid rate at which air viscosity rises with increasing air-pressure. Hence it is clear that when the dust particles reach a certan level their earthward progress will be practically arrested.

Meanwhile the region above this will be left impregnated with the smaller and lighter negative ions which are moving slowly or quickly in directions oblique to the earth's magnetic meridians and winding their way spiral-fashion towards the regions of the magnetic poles. The explanation of numerous astronomical, meteorological, magnetic, and atmospheric electric phenomena by the aid of this hypothesis of electrified solar dust projected by light pressure from the sun to the earth has been worked out in great detail by S. Arrhenius, K. Birkeland, W. J. Humphreys, and others. This solar dust hypothesis seems to be supported by the observations of Newcomb, Yntema, Abbot, and W. W. Campbell on the fact that on clear moonless nights the sky sends to us more light than can be accounted for by the sum total of starlight, and that this extra light is notably greater near the horizon than at the zenith, and also by the spectroscopic observations which show the green auroral line in all parts of the tropical sky on moonless nights.

In addition to this hypothesis of a permanently conducting upper region of the atmosphere we are compelled to postulate that beneath this there must be a region of variable ionisation due to solar light, which is ionised during the day above the level of clouds, dust, and water-vapour, but more or less dis-ionised during the night.

Dr. Eccles has worked out the consequences of assuming an atmospheric region in which ions of molecular mass are present, possibly formed by the action of ultra-violet light on molecular groups which are photo-electric. The presence of these heavy ions acts so as to produce what is in effect a reduction in the dielectric coefficient and therefore an increase in the velocity of electric waves through the ionised region.

This action may be illustrated by a magnetic parallel. If iron spheres were placed in a magnetic field they would be magnetised, but owing to the reverse action of the free poles the magnetic force in the iron would be less than the force at that point if the iron were not there. Hence the magnetisation produced is not that which corresponds to the external impressed magnetic force, but to the reduced magnetic force.

In the same manner if heavy ions are present in the air the orderly arrangement of them by the impressed field reduces the effective electric force in the space occupied by them, and this is equivalent to a reduction in mean dielectric constant. But the velocity of the wave is inversely as the square root of the dielectric constant, and therefore the wave speed is increased. From this it follows that if there is a gradually increasing density of heavy ions of both signs as we rise higher in the atmosphere, there will throughout that region be a gradually increasing electric wave velocity with height, and therefore an effect which has been called *ionic refraction* in virtue of which the higher levels of a plane electromagnetic wave advancing over the earth will advance more quickly than the lower parts. Hence the wave track will follow round the earth's curvature and an obliquely rising ray may even be brought down again to earth by an action resembling that of an inverted mirage.

The very complicated phenomena connected with freak signalling, the great effect on signal strength of the sunset and sunrise periods, the curious anomalies in the difference between daylight and night-time radio-transmission for various wave-length, and the variation in range between north–south and east–west transmission have all received certain plausible explanations on the theory of a variable ionisation by sunlight of the atmosphere, and its irregularities at the bounding surface of the earth shadow cone as it sweeps through the atmosphere. The atmospheric ionisation at this surface will tend to become "patchy," and will therefore bestow a certain increased opacity and increased reflecting power on that region for electric waves just as small air bubbles in water give it a certain opacity for visible light.

The general increase in range of radio-communication by night is accounted for on this theory as due to partial removal of the ionic refraction which in the daytime brings the ray down again to earth at ranges less than that due to the guiding properties of the permanently ionised higher layer.

There are, however, curious exceptions to this in the case of certain long-wave transmission. Senatore Marconi long ago pointed out that with certain wave-lengths from 5000 to 6000 metres transatlantic radio signals are often stronger by day than by night. These anomalies and others recorded by Dr. Eccles seem, however, to meet with reasonable explanations on the ionic refraction theory.

On the other hand, our difficulties are great in bringing these hypotheses to critical test. The atmospheric region in which the phenomena take place is far beyond the reach of our meteorological sounding balloons or possibilities of testing the actual ionic distribution. We can only, therefore, patiently

continue to collect the facts and trust to cautious inductive reasoning and observations to give us the true interpretation of them. All the phenomena seem, however, to point to the existence of three superimposed layers in the atmosphere: one, the higher, beginning perhaps above 80–100 km., which is permanently ionised with negative ions. The other, the middle, which has in part variable ionisation, depending on the position of that part with regard to the sun. The third or lower level has a relatively small ionisation, but electromagnetic waves travelling in it may have their energy considerably affected and reduced by the nature of the earth's surface over which they are moving. Powerful absorption is caused by some soils and by vegetation for certain wave-lengths.

From the earliest days of long-distance wireless telegraphy the difficulties in reception due to vagrant or natural electric waves and atmospheric electric discharges passing down the receiving aerial have been the bane of the wireless telegraphist. These waves create sounds in the telephone in aural reception which often drown completely the signal sounds and make false records in the case of printing or photographic reception. In the case of telephone reception, these noises have been classified into (1) rattling or grinding, (2) hissing, (3) clicking or snapping, and (4) crashing noises. These last two seem to be associated with thunderstorm conditions. Having regard to the fact that the positive atmospheric electric potential gradient of the earth increases at the rate of abou^ 100 volts per metre of ascent, it is not surprising that aerials several hundred feet high may be traversed by quite large currents, due to this cause alone, which may utterly swamp the feeble signal currents. The strength of a signal or noise in the telephone is generally estimated by its "audibility," and this is measured by ascertaining the resistance S of the shunt which must be put across the telephone of resistance R just to render the sound inaudible to a normal ear. The audibility A is given by the expression $A=(R+S)/S$. Hence the audibility is unity for a just audible sound. We can in this way measure the audibility of a signal on a background of disturbing noise, and a readable signal is generally obtained if the ratio of signal audibility to stray audibility is more than 25 per cent.

Owing to the serious extent to which these strays hinder regular reception, especially at certain times of the day and year, an enormous amount of attention has been given to their study and to the problem of eliminating them. They are most troublesome in the summer and during the night, and more severe in tropical than in temperate climes. Even in our latitudes they hinder reception at times immensely. Dr. L. W. Austin has stated that receiving at Washington, U.S.A., with a simple loop aerial from high-power radio stations in Europe with aerial sending currents up to 300 amperes, signals were unreadable for about 2000 hours a year. In tropical countries over long-distance circuits the power required to get a signal through may be often from six to eight times that which must be used at favourable times, and there are short periods when signalling is absolutely impossible. Having regard to the effect such interruptions have upon the earning power of a commercial station or upon certainty of communication in time of war or other urgent occasions, the problem of elimination of strays is perhaps the most important of all the practical questions connected with long-distance wireless telegraphy. It has been the subject of countless patents already. Early attempts went on the supposition that the strays were highly damped vagrant waves or had particular frequencies and could be eliminated by giving the receiving system a very pronounced resonance and making it a so-called stiffly-tuned circuit. These methods had a very limited application, for the reason that any impulse given to the receiving aerial sets it in electric vibration with its own natural period. Then, again, a number of inventions depend upon the peculiar properties of certain detectors, such as crystals and thermionic valves, in limiting the current which they pass or rectify. One most practically useful discovery was that by giving to the spark or wave train in the case of spark systems, or to the beats in the case of C.W. heterodyne reception, a regular frequency of 500 or 600, thus imparting a rather shrill musical sound to the signal, the ear could much more readily fasten attention on it even against a background of irregular but louder noise due to atmospherics.

Dr. de Groot made an immense number of observations on stray strengths at various hours of the day and months of the year about 1916 in the Dutch East Indies, and prepared diagrams showing the mean stray strength for various hours for each month of the year. From these he prepared a diagram giving the hourly stray strength during the day averaged throughout a year. The results were that in general the strays were more numerous and stronger during the night than during the day.

We have seen that there must be a certain intermediate but high-level region in the atmosphere in which the gases are ionised by the ultra-violet sunlight during the day, but re-combine again during the night. This region lies beneath the permanently ionised layer. In this permanently ionised layer there are drifting collections or masses of positively electrified and negatively electrified solar dust. If these masses are drawn together by their electric attractions or commingled, it is highly probable that electric recombinations will occur, which would generate electric waves. Suppose, then, that we assume the origin of a certain part of the strays to be in the upper permanently conductive layer of the atmosphere, these natural waves would find a certain obstacle to their downward transmission in the conductivity produced by the ionisation of the middle layer of the atmosphere by day. But at night-time this middle layer ionisation largely disappears and the natural electric disturbances in the upper layer would more easily find their way down to the earth. In other words, there would be a more unhindered access for the strays to descend. Hence in the night-time they would be more numerous

and more apparent in the effect they produce on receiving appliances.

The view that the strays which produce continuous rattling or grinding noises in the telephone have their origin in the high-level permanently conductive layer of the atmosphere was also put forward by Dr. de Groot, and he has employed ingenious arguments to obtain an estimate of the height of this layer, which he places at between 180 and 200 km.

These estimates must, however, be brought into comparison with the observations which have been made on the heights of the aurora. Störmer has made precise measurements of the parallax of the beams and arches of auroræ by photographic observations at places connected by telephone, and found, out of 150 observations, that the lowest occurred at 40 km. and the highest at 260 km. Much, however, depends upon latitude and the height of the region ionised by cosmic dust may be greater at the terrestrial equator than at the poles. The whole subject is of great importance in connection with meteorology and terrestrial magnetism, and invites the co-operation of physicists, astronomers and meteorologists, as well as radio-engineers.

The matter is, however, of such immense practical importance in radio-telegraphy that improvements or inventions connected with it are generally kept as carefully-guarded secrets, at least, for some time. Senatore Marconi spoke recently of inventions due to himself and his technical staff which promise a great advance in overcoming the interruptions of service due to strays, but details are at present withheld.

The problem of eliminating altogether the effect of strays on the receiver is at present the paramount one in long-distance wireless telegraphy, as they are a source of far greater difficulty than in short-distance working.

A Journal for Physical Measurements and Instruments.

READERS of NATURE, whether physicists or others, will be interested to learn of the steps which are being taken and the progress which has been made in connection with the proposed new journal dealing with physical instruments, the first important task which the newly founded Institute of Physics has set itself to accomplish. At the National Physical Laboratory the need for such a journal has long been felt; accordingly in 1919 the director addressed a letter directing attention to the needs of a number of Government departments and workers in various branches of science.

The response was most gratifying. The Admiralty, War Office, Ordnance Committee, engineering department of the Post Office, and other important bodies, all wrote approving the suggestion and in many cases offering support, while men of science—physicists, physiologists, miscroscopists, zoologists, and engineers—warmly commended the scheme, which also received the support of some leading instrument makers, including the British Optical Instrument Makers' Association and the British Electrical and Allied Manufacturers' Association. As a result the Institute of Physics brought the proposal before the Department of Scientific and Industrial Research. A meeting was held between representatives of the department and of the institute under the chairmanship of Sir J. J. Thomson, at which a suggestion was made that a single number might be prepared and issued as a specimen with the view of seeing what support could be obtained.

This suggestion was, at a later date, conveyed in a more formal manner to the department and approved by their advisory council, and a joint committee appointed by the department, the National Physical Laboratory, and the institute has been formed to give effect to it.

The institute has accepted financial responsibility for the publication of the journal provided scientific and industrial associations and individuals to whom the journal will be of service are prepared to furnish adequate guarantees for its support. The department will make a grant towards the cost of printing the specimen number.

The institute is to have the assistance of the staff of the National Physical Laboratory in the preparation of this number, and Dr. Rayner has, at the request of the committee, undertaken the duties of editor. An announcement of the proposed journal has been prepared and will be widely circulated along with a request for support, and it is hoped that the response will be such as to enable the institute to continue the task it has set itself and produce a work which will fill the acknowledged need.

Obituary.

SIR HENRY JONES.

IN Sir Henry Jones, professor of moral philosophy in the University of Glasgow, who died on February 4 at his home in Argyllshire, we lose one of our greatest teachers and, since Edward Caird, the leading representative of the Hegelian influence and tradition in English university life. A pathos surrounds the last few years of his life and also throws light on his personal character and strong mentality. He struggled against the painful disease which has proved fatal with a courage nothing short of heroic. He refused to give up, or even to slacken, his regular work. He persevered with his last undertaking, the Gifford lectureship, under conditions which few could have endured. He lectured even when speech was becoming

physically difficult, and he succeeded in delivering the first course. The second course has been interrupted by death, but the series of lectures is written and about to be published under the title "A Faith that Enquires."

Sir Henry Jones was born in 1852 in North Wales. In his twenty-third year he obtained the means to enter as a student in the University of Glasgow, and there came under the influence of Edward Caird, from whom he learnt the Hegelian idealism of which he was throughout his life an enthusiastic and consistent exponent. In 1878 he graduated with first class honours in philosophy and became Prof. Caird's assistant. After various appointments, and when Prof. Caird became Master of Balliol in 1894, he was appointed his successor and has held the chair since. He was an LL.D. of the University of St. Andrews, a D.Litt. of the University of Wales, and a fellow of the British Academy. He was knighted in 1912. He served on the Commission of Inquiry which preceded the Act for the Disestablishment of the Church in Wales. His name was included in the last New Year's honours list.

It is as a teacher that Sir Henry Jones will live in the memory of the many students who were inspired by him. As an author the value of his work is literary and social rather than scientific or philosophical. His books are popular expositions, marked, indeed, by keen appreciation and insight, but motived by strong moral enthusiasm rather than by any theoretical interest in investigating scientific or philosophic problems. His most important work in philosophy was a small volume on "The Philosophy of Lotze," published in 1894, which was for many years the chief source for English readers of their knowledge of the philosophy of the German professor.

PROF. V. GIUFFRIDA-RUGGERI.

DR. VINCENZO GIUFFRIDA-RUGGERI, professor of anthropology in the University of Naples, one of the leading anthropologists in Europe, died on December 21, after a brief illness. He was born at Catania, Sicily, in 1872, became a doctor of medicine in the University of Rome, 1896, and was thereafter appointed assistant to the professor of anthropology in that university, G. Sergi. He then commenced a career of extraordinary industry, contributing year after year some eight or ten original papers to the current literature of his chosen subject. Although Prof. Giuffrida-Ruggeri neither initiated any form of revolutionary idea nor opened any new chapter, yet his voluminous writings reflect more fully than those of any other writer the anthropological problems discussed by his contemporaries in Europe and America. The papers of his earlier years were devoted to studies of the skull, particularly of the face, but as time went on they broadened out into a study of human races in all parts of the world. He made a close study of the fossil remains of man, and in more recent years devoted himself to the evolution of man and to the origin and relationship of modern human races. The conclusions he had reached are set forth in two of his more recent books, "L'Uomo Attuale, Una Specie Collettiva" (1913), and "Su l'Origine dell' Uomo," 1921. By his death modern anthropology loses one of its most imposing and interesting figures.

A. K.

Current Topics and Events.

MME. CURIE was elected a free associate member of the French Academy on Tuesday—an event which marks a red-letter day in the history of feminism, and is a richly merited recognition of the memorable achievements of a woman who, although not French by birth, has conferred imperishable lustre on French science. So signal a distinction—unique in the history of that particular section of the Academy of which Mme. Curie becomes a member—is but the just reward for services rendered, not only to France, but also to the whole world, and brings honour to the illustrious body that has bestowed it. It was significant of the universal sentiment of approval with which Mme. Curie's candidature was greeted that her several male competitors should, one after the other, have waived their claims in her favour—a circumstance which adds a measure of grace to her triumph. On behalf of British workers in science—men and women—we beg to tender our warm congratulations to the new Academician, and trust she may long enjoy her well-earned *fauteuil* among the Immortals.

THE address of the president of the Paris Academy of Sciences, M. Georges Lemoine, published in *Comptes rendus* of December 12 last, refers to matters which must be kept in mind in England also. After pointing out the growing necessity for costly apparatus and laboratories in the progress of physical and natural science, M. Lemoine deplored the fact that the most important factor of all, namely, the man of science himself, is being more and more tempted to forsake the domain of science and to devote himself to industrial pursuits. Although the general rise of prices may partly account for this fact, it does not justify it. The supply of research workers from the universities and colleges is insufficient for national needs. It is absolutely necessary for the production of good work that the material conditions of existence should be assured for a much larger number of young men of science, at all events for a period of a few years. But there must also be an adequate number of posts, teaching and otherwise, free from anxiety as to the supply of daily needs and affording time for individual work, to which the young investigator can look forward as a future career. The address closes with an eloquent appeal to young people not to place too high a value on material wealth, but to remember the incomparable satisfaction which awaits the discoverer of new knowledge.

THE recent offer of a prize of 22,000*l.* by Lord Atholstan to the discoverer of a medicinal cure for cancer has been followed by one of 10,000*l.* by Sir William Veno for the same purpose. These offers have naturally created a good deal of interest, not only among the general public, but also among those engaged in the organisation and prosecution of cancer research. If successful treatment of this disease is going to be secured, it is certain that more financial support must be given to investigators than has been provided in the past. The present difficulties of this provision are so acute that Lord Athlone, the chairman of the Board of the Middlesex Hospital, has directed the attention of these intending benefactors to the urgent need of supporting existing researches. We are glad that this suggestion has been acted upon, for it is now announced that Lord Atholstan has given an additional 22,000*l.*, to be used for research work in cancer, and Sir William Veno has agreed that his gift should be used for research. It is possible that some further financial help may come for cancer investigation in this country as well as in others. Should this eventuate, it might well be the opportunity for some concerted action among the different cancer research centres. At present investigations upon causation or cure are unco-ordinated, and something might be gained by intensive work along avenues which a collective opinion would indicate.

AN earthquake of great interest, though by no means of the first order of magnitude, occurred on January 31 at 1h. 17m. 30s. p.m. (Greenwich mean time). In the United States the oscillations were so large that seismographs at Washington and Harvard University were temporarily put out of action. The origin was about 600 miles from San Francisco, 2420 from Ottawa, and 5140 from Oxford. In a letter to the *Times* of February 3 Prof. H. H. Turner locates it in lat. 42° N., long. 125° W., or about sixty miles from the coast where Oregon joins California. The shock is said to have been felt at many places along the Pacific coast as far as the Canadian border, and this seems to point to an elongated focus parallel, or nearly parallel, to the coast-line. It is interesting to notice that the epicentre lies along, or close to, the continuation, some two or three hundred miles to the north, of the San Andreas fault. Except for three short interruptions by the sea, this great fracture has been traced from Cape Mendocino on the north to the Colorado Desert on the south, a distance of more than 600 miles, and it was along its northern half, from Cape Mendocino to San Juan (about 290 miles), that the remarkable displacement occurred which gave rise to the San Francisco earthquake of 1906.

SOME disappointment has been expressed in Glasgow regarding the refusal of the managers of the Royal Infirmary to undertake the permanent retention on its present site of the old ward which was formerly occupied by Lord Lister, and in which his first successful experiments in antiseptic surgery were carried out. The infirmary has been largely rebuilt, and the old ward is said to obstruct the lighting and ventilation of the newer structure. The Lister Memorial Committee proposed to preserve the ward in perpetuity and fit it up as a museum of relics, portraits, etc. Failing in this purpose, the committee has now decided to devote its funds to the erection of a statue of Lister, near that of Lord Kelvin in the Kelvingrove Park, on the slope adjoining the University, in which they were colleagues as professors. The Lister relics collected by the committee will be displayed in the hall of the Pathological Institute at the Royal Infirmary. Meanwhile, no immediate steps are likely to be taken for the demolition of the old ward.

AT the meeting of the Royal Geographical Society on Monday, February 6, the president announced that this year's Mount Everest Expedition is already in movement. The definite sanction of the Tibetan Government has just been received, and Gen. Bruce has left England for India to make all the initial preparations, especially the organisation of a corps of Himalayan porters at Darjeeling. Lord Rawlinson has particularly attached himself to the expedition, and through his interest it has been possible to secure the services of Capt. Geoffrey Bruce, of the 6th Gurkhas, to help his cousin in the very important work of training, equipping, clothing, and feeding these porters. A second Gurkha officer has also been asked for. Besides these there will be six climbers, Lt.-Col. E. L. Strutt, Mr. Mallory (from last year's expedition), Mr. George Finch, Mr. Somervell, Dr. Wakefield, and Major Norton—all in the first rank of mountaineers. The veteran Himalayan climber, Dr. T. G. Longstaff, will accompany the expedition as physicist and naturalist, and Major J. B. Noel will act as photographer. Before the end of March these will all have arrived in Darjeeling, and a start will be made in time to reach the base camp near Mount Everest early in May.

THE National Institute of Industrial Psychology was founded in 1919 by the co-operation of Dr. C. S. Myers and other psychologists, with representatives of several well-known industrial firms, and it was finally incorporated in February, 1921. We now welcome the appearance of the first issue of the Journal of the institute, which is to appear quarterly. This journal aims at describing in non-technical language the methods and results of applying scientific knowledge to the human aspects of industry. It will publish accounts of research and propaganda work carried out, not only by the institute, but also by other similar bodies and by individual investigators, and will contain abstracts and reviews of books, reports, and periodicals. Amongst other contributions the present issue contains accounts of investigations on tin-box manufacture and on chocolate packing, in which it has been possible by the introduction of simple improvements in the methods of work to improve output by 30 to 40 per cent., and at the same time to diminish the fatigue of the workers. The assistant director of the institute, Dr. G. H. Miles, discusses vocational guidance, and Mr. Eric Farmer describes the reduction of

fatigue through the adoption of rhythmical methods of work in various industries.

A SUGGESTION has reached us from Mr. F. J. W. Crowe, St. Peter's House, Chichester, that fine concrete might be used for making mirrors of large size and accurate surface such as are employed in large reflecting telescopes for astronomical work. Dr. J. W. French, of the firm of Messrs. Barr and Stroud, to whom we submitted the communication, is of the opinion that such a surface would not be satisfactory. Silvering shows up minute defects very plainly; in fact, rustless steel is the only material other than glass which gives reasonably good results, and to grind a plaster surface with the necessary accuracy would be almost impossible on account of the way in which all plasters absorb water. The greatest difficulty to be met, however, is the distortion which occurs when plaster sets. Both at the time of setting and afterwards there are rapid crystalline changes which may continue for at least one year. Any plaster containing unslaked lime will undergo distorting changes which would make the production of a good optical image impossible. This defect might be remedied by using a blend of cements, but, unfortunately, they are not of a kind that could be worked to give a good continuous surface.

IN a report to the Mercantile Marine Department of the Board of Trade on the proposed standard of rejection of seamen for colour-blindness, Dr. Edridge-Green states that 5 per cent. of men have diminished colour perception. As there is a gradual change from normal to absolute colour-blindness, it is difficult to fix a point at which it shall be considered that colour-blindness incapacitates a man from work as a seaman. The Nautical Advisers of the Board of Trade agree that a man who can distinguish between red, green, and white lights a mile distant shall be considered competent. Dr. Edridge-Green finds that the men who fail under this test can see only three or less distinct colours in the spectrum, while those who pass the test see four or more. He therefore fixes the line of demarcation between those who can distinguish red, yellow, green, and violet and those who see only red, green, and violet in the spectrum.

THE National Institute of Botany has recently issued a very encouraging Second Report (1920–21). During the year the headquarters at Cambridge were completed and came into use, the official Seed Testing Station being transferred thereto in September last. Within a month a private visit was paid by their Majesties the King and Queen and Princess Mary, who expressed their appreciation of the importance of the work carried on. In order to bring the institute into closer touch with the agricultural community a fellowship is being established (annual subscription one guinea), in which Mr. Lloyd George has asked to be enrolled as one of the first life fellows. For the welfare and progress of the work it is essential that a considerable income be raised by annual donations and subscriptions, and it is hoped that very many agriculturists will avail themselves of the opportunity of assisting in this by becoming fellows. In the crop improvement branch, field trials of cereals have been established, "preliminary trials" being made to provide seeds for "full trials" which will last for two years. A collection is also being made of stocks of varieties of cereals, especially of historical varieties of wheat, some of which are rapidly disappearing. An interesting feature of the current year's work will be an exhibition of yield trials of growing cereals and potatoes on the Royal Agricultural Show ground in Cambridge. At Ormskirk the immunity and maturity trials of potatoes have been continued; they indicate that the system of experiment used promises to lead to satisfactory results when modified and extended over a longer period of time. The official Seed Testing Station reports a considerable increase in the year's work, in spite of the disorganisation due to the transfer from London. It is proposed to hold a summer course for the training of seed analysts, and a handbook of seed-testing methods is in preparation. An International Conference on Seed Testing at Copenhagen was attended by representatives of the institute, and it is hoped that the next conference in 1924 will be held partly at Cambridge.

IN the French newspaper *Savoir* for December 24 last Prof. Capitan discusses Mr. Reid Moir's discoveries of worked flints at the base of the Crag near Ipswich and in the Forest Bed near Cromer. He concludes that the simple chipping round the edges of these flints is undoubtedly the work of man or one of his precursors. He therefore agrees that Mr. Reid Moir has found definite evidence of Pliocene man in Britain.

SIR OLIVER J. LODGE will deliver the fifth Silvanus Thompson memorial lecture at a special meeting of the Röntgen Society to be held on Tuesday, March 21, at the Institution of Electrical Engineers.

ON Thursday next, February 16, Prof. Arthur Perkin will begin a course of two lectures at the Royal Institution on "Dyeing: Ancient and Modern"; and on Saturday, February 18, Prof. Ernest Gardner will deliver the first of two lectures on "Masterpieces of Greek Sculpture." The Friday evening discourse on February 17 will be delivered by Prof. D. S. M. Watson on "The History of the Mammalian Ear."

THE annual general meeting of the Institute of Metals on March 8–9 will be held at the Institution of Mechanical Engineers. On the opening day of the meeting the new president, Mr. L. Sumner, will deliver his inaugural address, and in the evening the annual dinner of the institute will be held at the Trocadero Restaurant, Piccadilly Circus, W.1. Papers on the constitution and properties of copper and aluminium and their alloys will occupy the scientific sessions of the meeting.

IN the annual report of the Physical Society to be presented at the annual meeting to-morrow, February 10, it is stated that Prof. A. Fowler has prepared for the society a report on "Series in Line Spectra," which will shortly be issued. A second

report on "Atomic Structure," by Prof. Bohr, is in preparation. An appeal for funds for a Duddell memorial medal resulted in a sum of about 650*l.* being raised. The committee dealing with the memorial has asked Mrs. Mary G. Gillick to undertake the preparation of the medal, which it is hoped will be ready during the early part of 1922.

THE following lecture arrangements have been made by the Royal College of Physicians of London :—The Milroy lectures on "The Influence of Industrial Employment on General Health," by Dr. Major Greenwood, on March 9, 14, and 16; the Goulstonian lectures on "The Interpretation of Symptoms in Disease of the Central Nervous System," by Dr. A. Feiling, on March 21, 23, and 28; the Lumleian lectures on "Diseases of the Thyroid Gland," by Dr. H. Mackenzie, on March 30 and April 4 and 6. The lecture-hour in each case will be 5 o'clock.

IN a paragraph in NATURE of February 2, p. 151, it was suggested that the list of British research chemicals issued by the Association of British Chemical Manufacturers should be revised and issued as soon as possible. Mr. W. J. U. Woolcock, general manager of the association, informs us that the suggestion has been anticipated, and that a revised and enlarged edition of this list is at the moment in the press. Not only will this second edition contain a larger number of organic chemicals, but inorganic chemicals will also be included.

MANY libraries doubtless contain duplicates of astronomical periodicals and books that are needed in other institutions. For the purpose of facilitating their purchase, exchange, or gift, the National Research Council contemplates the compilation of a list of all duplicates that can be spared. This list will be mimeographed and widely distributed. Those who have duplicates to dispose of are asked to send a list of them to the National Research Council, Division of Physical Sciences, 1701 Massachusetts Avenue, Washington, D.C., U.S.A. A copy of the complete list will be sent on application.

Our Astronomical Column.

CONJUNCTION OF MARS WITH A STAR.—Mr. W. F. Denning writes :—The planet Mars will make a very near approach to the star β Scorpii (third magnitude) on the night of February 22. Mars will rise at 1.35 a.m. on the morning of February 23, and the planet may be observed if the sky is clear from that time until sunrise, with the star lying slightly to the north-west. It will be interesting to watch the gradual approach of the two objects from the present time up to the date of conjunction, and then to follow them as the distance between them becomes greater from night to night. On February 10 Mars will be 7° west of the star, and on March 7 7° east, its motion carrying the planet daily about half a degree eastward. The near approach of the two objects may be followed with the unaided eye, though the view will be much improved by means of a field-glass or telescope.

COMET NOTES.—H. Mahnkopf gives the following search ephemeris for comet 1916 I (Taylor), due at perihelion about 1922 June 13. It is for Greenwich midnight. Magnitude about 15:

		R.A. h. m.	S. Decl. ° ′			R.A. h. m.	S. Decl. ° ′
Feb.	10	1 26·1	4 21	Feb.	26	1 54·5	0 5
	14	1 32·8	3 18				N. Decl.
	18	1 39·8	2 14	Mar.	2	2 2·2	1 0
	22	1 47·0	1 10		6	2 10·2	2 6

Log r, log Δ, February 2, 0·303, 0·357; February 18, 0·284, 0·368; March 6, 0·264, 0·376.

A new very faint comet, 1922*a*, was discovered by Mr. W. Reid at the Cape on January 20; its place on January 24d. 9h. 34·3m. G.M.T. was R.A. 9h. 54m. 30·9s., S. decl. 33° 46′ 31″; daily motion *minus* 56s., south 7′.

INTERNAL MOTIONS IN THE SPIRAL NEBULA M 81.—The *Astrophysical Journal* for December contains Mr. van Maanen's discussion of the internal motions in this spiral deduced from two photographs taken with the 60-in. reflector at Mount Wilson at an interval of eleven years. The results of an earlier discussion based on a six-year interval are in all cases confirmed in sign, but the numerical values are considerably increased. Taking 0·001″ as unit, the mean of 104 points measured gives the rotational component as 38, the radial component outward as 13, the stream motion (along the whorls of the spiral) as 39, and that transverse to the whorls as 7. The indicated periods of rotation about the centre for four spirals are :—For M 101, 85,000 years; for M 33, 160,000 years; for M 51 (Canes Venatici), 45,000 years; and for M 81 (Ursa Major), 58,000 years. These figures are all much smaller than any possible period of rotation of the Galaxy, and seem to indicate an entirely different character for these objects. The only possible way of avoiding this issue would seem to be the adoption of Dr. Jeans's suggestion that the Galaxy was originally much more compressed than it is now, so that its period of rotation would have been shorter.

It is, however, emphasised, that the motion is not pure rotation, but outward along the spiral arms. The figures given have been corrected for foreshortening, the plane of the nebula being inclined 49° to the celestial sphere. The proper motion of the nebula referred to fourteen faint comparison stars is +0·014″ per annum in R.A. (great circle) and −0·005″ in dec.

Sixty-three stars in this region, of about the ninth magnitude, have a mean motion of −0·0014″ in R.A. and −0·0047″ in dec. (Greenwich Astrog. Cat., vol. 4). It is therefore probable that the greater part of the motion of the nebula in R.A. belongs to it, and not to the stars.

The author considers that the character of internal motion established in several spiral nebulæ supports Dr. Jeans's theory that the spiral form is due to tidal action arising from the approach of two nebulous masses.

Research Items.

Culture of Ancient Peru.—One difficulty in the sequence-dating of the textiles of ancient Peru, which, with the pottery, are the best evidence of the pre-Spanish culture, is that Peruvian looms are very scarce in museums, and, when found, are usually incomplete, and almost invariably undatable, even in accordance with the sequence-dating at present accepted. In *Man* for December last, Mr. T. A. Joice reports that a vase presented to the British Museum in 1913 by Sir Herbert Gibson shows a definite and indisputable correlation between a certain type of loom and a certain type of pottery. This vase, which definitely belongs to the Proto-Chimu period, that is to say, the earliest period of any sort of developed culture on the northern Peruvian coast, presents a scene showing the weaving of tapestry on a loom without a treadle, and associated with pottery also belonging to the same early period. It does not prove, but it suggests, that the principle of the treadle was unknown to the Proto-Chimu weaver; if so, then the treadle belongs to a comparatively late period of South American culture. Much further inquiry is needed before the significance of this discovery can be used as a proof of sequence-dating.

Parasitic Worms from Animals.—Dr. G. A. MacCallum gives (*Zoopathologica*, vol. 1, No. 6, 1921, published by the New York Zoological Society) an account of parasitic worms from animals in the New York Zoological Park and Aquarium, with a figure and brief description of each species; some of the descriptions, however, are too brief and not altogether serviceable. A new species of Heronimus is viviparous—the uterus contains miracidia. The author, who is pathologist to the New York Zoological Society, deserves commendation for his zeal in searching for and recording the parasites of the animals which pass through his hands.

Indian Marine Polychæta.—A further instalment of the reports on the fauna of the Chilka Lake has been published in vol. 5, No. 8, of the Memoirs of the Indian Museum. This part contains a systematic account of the Polychæta by Mr. R. Southern, who also reports on collections from the Gangetic delta and from the Cochin backwater. The majority of the species live either in brackish water of low salinity or are euryhaline, *i.e.* can live in water the salinity of which varies between wide limits. Euryhaline forms appear to be relatively more numerous in India than in Europe, and Mr. Southern suggests this adaptation may be correlated with the sharp division of the climate into wet and dry seasons, one result of which is that the littoral region, especially in bays and estuaries, is periodically flooded with water of low salinity. Mr. Southern points out that there are so few records of Indian littoral marine Polychæta that there is no basis for instituting a comparison between the Polychæta of the lake and those of the seashore. Of the twenty species from the lake, eighteen are described as new. The collection has a typically marine facies, and probably represents an impoverished remnant of the Polychæta which inhabited the open bay before the present lake was almost completely cut off from the Bay of Bengal by the spit of sand which forms its eastern boundary.

Selection Experiments with Cladocera.—Dr. A. M. Banta has published (Carnegie Institution of Washington, Publication No. 305) the results of extensive selection experiments with Cladocera. He chose responsiveness to light, as measured by reaction-time, and selected simultaneously in different strains for increase and decrease of this physiological character. Pure lines of Simocephalus and Daphnia have been bred parthenogenetically for more than eight years. In such parthenogenetic eggs there is only one maturation division, and in the absence of a reduction division there is apparently no opportunity for segregation or recombination of genetic materials. In the course of the experiments a great deal has been learned about the biology of the organisms, and their reactions to varying environments. Selection experiments produced a significant difference between plus and minus strains in only one of fifteen distinct lines studied, although there were indications of an effect in several others. The nature of this effect of selection is discussed at length. The change appears to have been a gradual one, which can scarcely be accounted for by the occurrence of a few marked mutations. The two strains obtained differed only in reactiveness to light, and this difference was maintained for at least 112 generations after selection ceased. These results would appear to limit the universal application of Johannsen's law that selection within the pure line is of no avail in modifying its genetic properties.

Factors of Growth and Multiplication.—Two recent papers (*Biochemical Journal*, vol. 15, pp. 595–612) by Prof. Brailsford Robertson contain some important observations on the mutual influence of individual organisms in promoting growth and multiplication. Working with the ciliated protozoon Enchelys, he shows that it feeds mainly upon bacteria, and that its rate of growth is much influenced by some soluble thermostable substance which arises from them. During the early stages of development of a culture the multiplication rate increases progressively with each division, and partakes of the autocatalytic character which has been previously described in various animals and plants from man downwards. This has nothing immediately to do with its food, but depends on the contiguity of the infusoria, and in a special series of experiments Prof. Robertson shows that a culture started with two individuals will produce, not twice, but about five times as many descendants in twenty-four hours as a culture started with a single Enchelys. Conjugation was never seen under the conditions of the experiments, and the effect appears to be due to some accelerator substance produced by the protozoa in the presence of the accelerator arising from the bacteria. It would be of much interest to determine whether the same phenomena accompany the growth of an organism feeding only on soluble substances such as the bacteria-free race of the ciliate Colpidium described by Dr. Peters (*Journal of Physiology*, vol. 55, p. 1), where the conditions are much simpler than those examined by Prof. Robertson.

Mixed Products of Granitic Intrusion.—Mr. Charles H. Clapp, in his study of "The Geology of the Igneous Rocks of Essex County, Massachusetts" (U.S. Geol. Survey, Bull. 704, 1921) makes a noteworthy claim for regarding several unusual types of rock as products of the intermingling of an invading granite with material derived from the cover into which it penetrates. He recognises a gravi-

tational differentiation during crystallisation as accounting for the production of an underlying gabbro-diorite and an overlying granodiorite from an original basaltic magma; but granite afterwards intruded into the more basic of these masses, and has produced a number of "hybrid" rocks. The gabbro-diorite was cold at the time of this intrusion, and thus lent itself to extensive shattering, and the detached blocks have been melted up on an extensive scale. From analogy with undoubted composite products, the author considers that the well-known "essexite" of Salem Neck, consisting of the minerals of gabbro side by side with species more rich in sodium, has arisen from similar intermingling and recrystallisation.

PETROLEUM RESOURCES OF CALIFORNIA.—The geology and petroleum resources of North-Western Kern County, California, have been dealt with in a bulletin of the United States Geological Survey (No. 721) recently to hand. New information concerning this interesting region is always welcome, and the oil prospects of this part of the San Joaquin Valley, with its bordering hilly country, would seem to be decidedly favourable. The area described embraces the already developed fields of Belridge and Lost Hills, which produce oil from Miocene beds, the structures being essentially anticlinal; prospective areas are suggested in the Temblor Valley (hill region) and in the San Joaquin Valley itself, though in the latter instance "wild-cat" drilling will probably have to be resorted to on account of the thick covering of alluvium masking the solid geology. The detailed work of the California State Mining Bureau on the study of underground structural conditions as affecting development and production of existing fields is now in progress, and as results accrue some further valuable information should eventuate which may have a far-reaching influence on the progress of development of the untested areas here described.

DAY AND NIGHT DISTRIBUTION OF RAINFALL.—The differences between summer daytime and night-time precipitation in the United States are the subject of a communication by Mr. W. J. Humphreys in the *Monthly Weather Review* for June last. A chart based on about 175 Weather Bureau stations is given showing the percentage of average precipitation that occurs at night, 8 p.m. to 8 a.m., for the season April to September over the United States. The various percentages of the twenty-four hours' rainfall that occur at night in different portions of the United States during the summer are shown by curves for each 5 per cent. from 25 to 65. Referring to the inequalities between the day and night distribution of summer rainfall, and accepting this as due to the distribution of thunderstorms, it is stated to be consequently in substantially the same proportion as is the strong vertical convection of tolerably humid air. The map shows very markedly that in the south-east portion of the United States the summer rains are most frequent during the day, and the author states that most of these rains are due to heat thunderstorms resulting from convection induced by strong surface heating. The excess of rains in the daytime in some other parts of the United States is similarly explained. Consideration is also given to the regions in which the summer rain is most abundant by night, and various causes are put forward. The movement of cool anticyclones is asserted as exercising considerable influence in the main by "breaking" the "hot waves" of the Mississippi, Missouri, and Ohio valleys, thunderstorms being developed. In parts the cooler air is said to overflow the warmer, and thereby establishes that convectional instability essential to the genesis of the thunderstorms. In this way the author is of opinion that in parts at least the thunderstorm is more frequent and the summer precipitation more abundant during the night than during the daytime.

GRAVITY OBSERVATIONS.—The United States Coast and Geodetic Survey has issued as a Special Publication (No. 69) a report by Mr. Clarence H. Swick on "Modern Methods for Measuring the Intensity of Gravity." The instruments and methods, which are dealt with in usefully great detail, are those employed by the Survey for their gravity expeditions. The determinations are made with half-second (quarter-metre) pendulums, which in 1890 replaced the metre pendulums formerly used. This step marked an epoch in the gravity work of the Survey; the change not only greatly reduced the cost of transport and of preparing the stations, but also increased the accuracy so much as to render the observations prior to 1890 obsolete as material for investigations into the theories of gravity and isostasy. The observations made are relative, the time of oscillation of the pendulums measured at each station being compared with the corresponding times at the pendulum-room of the Survey in Washington, where the absolute value of gravity has been carefully determined. The pendulums are swung at low pressure in an airtight case, and corrections are applied for temperature, pressure, arc, flexure, etc. An interferometer is used to determine the flexure of the pendulum support. Up to 1920 the number of gravity stations "occupied" with the modern instruments was 276, of which 230 were established since 1909. In 1920 a further important instrumental improvement was introduced by the construction of pendulums with invar instead of bronze; the reduction of the temperature-coefficient to one-fifteenth its former value greatly simplifies the observing conditions. Another advance is the use of wireless signals for determining the chronometer rates. The report closes with an interesting appendix instructing the observer in the art of justifying his work to the lay citizen of the United States, by explaining briefly the purpose and value of gravity observations.

TESTS OF WELDLESS STEEL TUBING.—A paper by Mr. W. W. Hackett read before the Institution of Automobile Engineers gives an account of a large number of alternating stress experiments on weldless steel tubing such as is used in motor-cycles and on components, *e.g.* motor-cycle forks. These experiments enable the author to make several suggestions for improvements in constructional details. He also makes out a case for the use of tubes made from steel containing a higher percentage of carbon than has formerly been accepted. From experiments carried out during the war period on aeroplane tubing it was found that excellent results could be obtained by using 0·5 per cent. carbon steel tubing, giving in the bright or blued state a yield of 40 to 45 tons per sq. in. and an ultimate stress of 45 to 50 tons per sq. in.; when annealed, the steel should give 23 tons per sq. in. yield and 35 tons per sq. in. ultimate. The author has found that in the motor trade there was no inclination to use these high-carbon steel tubes, for it was feared that they would be brittle. The author's tests were carried out on joints brazed in his shops in a commercial manner, and show consistently that the 0·5 per cent. carbon steel has always been superior to 0·3 per cent. steel, and that the latter has always been better than 0·15 per cent. steel.

Botany at the British Association.

(a) *The Oldest Land Flora.*

THE Edinburgh meeting will be long remembered among botanists as that at which a consideration of the oldest land flora, namely, that of the Rhynie Chert beds, took a prominent place. This subject bulked largely in the president's address; it formed the basis of a series of papers presented to a joint meeting of the Sections of Botany and Geology, and it was fully illustrated by a marvellous series of microscope preparations demonstrated by Dr. Lang and Dr. Kidston in the laboratory of the Royal Gardens.

The Rhynie Chert beds of Devonian age contain identifiable remains of algæ, fungi, and bacteria, but the chief interest attaches to the forms which, though classified as vascular cryptogams, present in many respects little more differentiation than a seaweed, and, indeed, show many resemblances to some of the higher seaweeds of the present day. They are leafless and rootless forms bearing sporangia scarcely differentiated from the vegetative portion of the axis. Nevertheless, they are undoubted land plants, as shown by "the presence of water-conducting tissue and stomata and by manifestly air-borne spores." The function of roots was apparently performed either by root-hairs or by special branches of the rhizome. The spores were usually borne on terminal sporangia which were evidently fertile branch endings.

Dr. Lang described the plant remains found in these beds, and more particularly those of the vascular forms constituting the family of the Rhyniaceæ, viz. a filamentous alga probably allied to the modern blue-greens; another form which appears to be connected with the Characeæ; and a fragment of the supposed seaweed Hematophyton, showing for the first time its external characteristics, together with several members of the fungi. The Rhyniaceæ include *Rhynia major* and *R. Gwynne Vaughanii, Hornea Lignieri,* and *Asteromyelon Mackei,* the latter with its small investing leaves being the most complex. The vascular tissue is of a very simple order, the water-conducting elements being spirally thickened and the phloëm elements large and thin-walled with oblique ends. The latter tissue is continuous with a central column in the sporangial heads, recalling the columella of the mosses.

The vertical distribution of the various forms in the peaty beds of the chert indicates that petrifaction occurred in the lower parts of the bed while plants were still growing on the higher parts. Probably the irritating action of vapours from a volcanic fumarole in the neighbourhood caused the necroses and swellings observed on the plants.

Dr. Horne stated that recent work pointed to the Continental origin of the deposit and indicated that the Rhynie plants actually grew where they were preserved.

Dr. Kidston concluded that if Asteroxylon were flattened out and preserved as an impression it would resemble very closely the middle Devonian species called *Thyrsophyton Milleri,* and he believed that the fact afforded some indication of the Middle Old Red Sandstone age of the Rhynie bed.

Several of the later speakers directed their remarks more to the theoretical importance of these discoveries and their relation to modern theories of evolution. This had been dwelt upon at some length by Dr. Scott, who emphasised the present-day lack of unanimity with regard to the nature and extent of variation as the material upon which evolution works. Dr. Lotsy pointed out the dilemma summed up in the phrases "like breeds like" and "like may breed unlike." He thought that the great phyla were widely separated, and had possibly separate origins, and while for *classes* of plants, as generally considered by the palæobotanist, the first phrase emphasised the truth, when the smaller units or *species* were considered it was clear that frequently "like breeds unlike."

(b) *Forestry and its Problems.*

A whole day was devoted to forestry, the Botany and Zoology Sections holding joint session during the part of the programme concerned with insect problems. Mr. J. Sutherland, Assistant Commissioner for Forestry in Scotland, gave a very complete account of the past and present position of forestry in Great Britain, and enumerated in an exhaustive manner the advantages of a consistent State policy of extended afforestation. The new forestry policy now provides that the 3,000,000 acres of 1914 shall be increased during the present century by 1,750,000 acres of coniferous trees, and that two-thirds of the programme shall be completed during the next forty years. This programme cannot, however, be put into actual effect without the co-operation of landowners and State. A large proportion of money expended in forestry becomes available as wages, and consequently it provides a great stabilising influence in keeping workers in rural areas. He quoted the increase of population from 69,000 to 289,000 which has taken place in the Landes Department of France as a result of afforestation. He further indicated the immense importance of forests in time of war.

Prof. Stebbing traced the history of Indian forestry since 1850, when a committee of the British Association was set up at the instigation of Dr. Cleghorn "to consider the probable effects from an economic and physical point of view of the destruction of tropical forests in India." The result of the efficient management of the Indian Forest Department shortly afterwards set up has been a plentiful supply of forest products and a considerable annual revenue.

Dr. Borthwick and Prof. Henry both urged the importance of selecting the varieties most suitable to the climatic conditions found in the country, and expressed the opinion that the State might reasonably undertake the protection of forests from devastating fires.

(c) *Quantitative Analysis of Plant Growth.*

The discussion on "The Quantitative Analysis of Plant Growth" was introduced by Dr. Lawrence Balls, who illustrated his points largely by reference to the cotton plant. The problem of plant growth is a physico-chemical one, and therefore must be explored by quantitative methods and checked by statistical treatment. Dr. Balls hinted at the possibility of elucidating geometrical constructions in the cell parallel to those established by Dr. Church for external form. This would furnish developments akin to those which the study of atomic structure has brought to the physicists. The recent advance in physiological thought as well as in actual technique gives us reason to expect rapid increase of knowledge even in so intricate a problem as that of growth.

Contributions to this discussion were made by Messrs. Briggs, Kidd, and West on "The Quantitative Study of the Growth of *Helianthus annuus,*" and by Prof. Priestley and Miss Evershed on "A Quantitative Study of the Growth of Roots."

(d) Some other Papers.

The papers delivered before the Section dealt with a diversity of subjects. Mr. Matthews contributed a paper on "The Distribution of Certain Elements of the British Flora." These show peculiarities of geographical distribution in Great Britain which, when studied cartographically and compared with their occurrence on the Continent, seem to furnish additional evidence in favour of the views of some of the earlier students of the problems of plant repopulation after the Glacial period. The Palæarctic flora of post-Glacial times is now confined to the highest Scotch mountains, and has been replaced elsewhere in Great Britain by a temperate flora from the Continent.

Mr. Hamshaw Thomas gave an account of his investigations into the structure of some angiospermous fruits discovered in the Middle Jurassic rocks of Yorkshire. Each fruit, which shows traces of what may be a stigma, contains about eight small seeds clothed with a double fibrous integument. While the specimens are obviously Angiosperms in that the seeds are developed inside a fruit-wall, the seeds themselves show resemblances to some of the primitive Gymnosperms or Pteridosperms, and may yet throw light on the origin of the flowering plants, that difficult problem referred to by Charles Darwin as an "abominable mystery."

Prof. McLean Thompson, in his account of the floral development of the cannon-ball tree and its bearing on the floral morphology of the Myrtales, put forward the view that the gigantism of cells and sterility of pollen found associated with the floral lopsidedness had arisen as a mutation.

Dr. Batten gave an account of the organs of attachment in Polysiphonia; Miss Saunders put forward a theory of the morphological nature of the Dicotyledon shoot, viz. that each internode consists of an axial core clothed with a skin of the extended bases of the leaves immediately above.

Major Hurst's paper on "The Origin of the Moss Rose" raised many interesting problems, particularly in view of the recent cytological work on this genus. Täckholm and Blackburn and Harrison ascribe hybridity as the cause of the irregular distribution of unpaired chromosomes found to be associated with abortive pollen. Darwin's view that the moss rose is a bud variation of the familiar cabbage rose (*Rosa centifolia*) seems to be confirmed. The moss rose would appear to have arisen as a mutation, and to have been in cultivation only since the end of the seventeenth century, while the cabbage rose has been cultivated for more than two thousand years. In conclusion, Major Hurst expressed his views thus:—"In terms of the recent development of the chromosome theory of heredity it may be said that the *moss* mutation arose through the presence of an additional factor in a single locus of a single chromosome of a somatic cell."

"The Behaviour of the Somatic Nucleus in Development" formed the subject of a paper by Prof. McLean, who described briefly the discovery of the binucleate phase, and discussed its significance in relation to senescence, normal histogenesis, and somatic segregation of characters.

The eminent Dutch botanist, Dr. J. P. Lotsy, furnished a paper on "Factors of Evolution." He deprecated the custom of tracing the course of evolution through the genealogy of species which exist only as a conception. Nature produces individuals, some of which interbreed freely and may be termed "syngameons," and these have been mistaken for species. The course of evolution should rather be traced by the genealogy of the gametes, and the questions of fundamental importance are: Can a gamete vary by itself without loss of chromosomes? And are such variants transmissible? The only transmissible changes proved to occur are the results of crossing, and they transgress the limits of the Linnean species. Not enough attention has yet been given to the crosses between gametes differing in the number of chromosomes and the consequent irregular distribution which causes changes that may even simulate Mendelian segregation.

Mont Blanc Meteorological Observations.

The seventh volume of Annales de l'Observatoire Météorologique Physique et Glaciaire du Mont Blanc (altitude 4350 metres) has now been published, under the direction of M. J. Vallot, founder and director of the observatory, following the sixth volume which was published in 1905 (tome 7, Paris, G. Steinheil, éditeur, 1917). It records the death of Janssen in 1908 and the transformation of the provisional society of his observatory at the summit (4808 metres) into a *société définitive* which placed that observatory also under the direction of M. Vallot. Both were utilised in 1908, but that on the summit became not merely uninhabitable, but dangerous, and it was therefore demolished in 1909. Since that date work has been carried on only at M. Valot's observatory, which he had placed at the disposal of the society. The volume referred to deals only with the work accomplished before the union of the observatories. The researches made at the cost of the society have been published *en résumé* in the *Comptes rendus*; those which cannot find a place there, as well as reports *in extenso*, will appear in later volumes of the Annales.

The publication of the seventh volume has been delayed by M. Vallot's ill-health and by the war. It contains two papers by M. Henri Vallot, one on some modern maps of the massif of Mont Blanc, the other on the progress made with the map on the scale of 1 : 20,000 by the brothers Vallot; also some "Notes expérimentales sur le mode d'action des cures d'altitude," by M. G. Kuss, of the Sanatorium d'Angicourt. The greater part of the volume is occupied by an elaborate discussion by M. J. Vallot of the barometric calculation of altitudes, particularly on the correction for the diurnal variation of the temperature of the air, which with the ordinary formula may cause differences of as much as a hundred metres in the estimation of a difference of level of 2800 metres. The discussion leads up to the suggestion for correcting the value of the difference of height obtained by the "classical" tables by a correction based on the mean temperature of the day for the base station, on a temperature for the upper station obtained from the base temperature by subtracting one degree for every 154·5 metres, and on a special correction for diurnal variation of temperature based on a month's observations in 1887 of Mont Blanc with reference to Geneva. Suitable winter values have still be to be ascertained. Examples of the application of the method are given and a defence of the procedure in view of recent work on the subject, which is of practical importance for meteorological maps as well as for Alpinists. It is, however, full

of difficulty in consequence of the changing thermal character of the air column between stations at different levels. Perhaps the diurnal variation of pressure affords the best line of approach. A proper formula regularly applied to observations at the top ought to give a diurnal variation of pressure at the base comparable with that obtained from direct observations at the bottom. What M. Vallot calls the "classical" method would certainly not do so. There is an interesting paper by Buchan on experiences at Ben Nevis which bears upon the subject.

NAPIER SHAW.

Sponge-spicules.

PROF. DENDY'S memoir (in *Acta Zoologica*, 1921, pp. 95–152, 50 figures) on the evolution of the tetraxonid sponge-spicule will appeal equally to those interested in problems of evolution or in sponge-spicules from the point of view of form and of their great taxonomic value. It is not only possible to arrange these spicules in an apparently phylogenetic series with a degree of completeness which is perhaps unparalleled in any other group of the animal kingdom, but the structure of the spicule itself, and the different forms which it assumes, are relatively so simple and definite that the problem of accounting for them in terms of physiological or physico-chemical processes seems far more capable of solution than similar problems among the higher animals. Prof. Dendy describes the forms of spicules of the primitive Plakinidæ, showing that they can all be derived from the tetract, and discusses concisely the evolution of megascleres (tetract, diact, and monact) and microscleres (polyact and diact) and the development of spines leading to the pseudopolyact forms. He also puts forward provisional conclusions as to the development of a spicule. Two kinds of cells—initial cells and silicoblasts—are concerned in spicule formation; the former cells secrete the organic material (spiculin) which forms the axial thread or protorhabd around which the silicoblasts collect and deposit silica. A growing spicule may come to be completely enveloped by a silicoblast, which has accordingly been regarded by nearly all observers as the mother-cell in which the spicule originates. In many cases the number of initial cells increases by cell-division as the spicule grows, and the development of spines and other outgrowths on the primary spicule is effected by the establishment of secondary growing points at the places where spiculin is deposited by initial cells. The causes which determine the form of the spicule are briefly considered, and though some of the characters of spicules are adaptive the vast majority are non-adaptive; for adaptation in spicule-form, where such exists, no satisfactory explanation seems to be forthcoming. To say that some "instinct" directs an amœboid silicoblast containing a spicule towards the gemmule or towards the surface of a sponge is, as the author remarks, not an explanation.

Iron Production in India.

THE *Journal of Indian Industries and Labour* for November last (vol. 1, part 4) contains, amongst other interesting matter, a summary of the present position of iron production in India which deserves the serious attention of all engaged in iron and steel industries. The large and rapidly developing coalfields, the enormous deposits of high-grade hæmatite iron ore, ample supplies of limestone and of refractory materials, abundant and low-priced labour, all combine to place India in the position of a very serious potential competitor in the world's markets. Two firms are producing iron to-day—the Bengal Iron Co., with works at Kulti, on the Barakar River, comprising five blast furnaces, each with an output of 450 tons of pig-iron per twenty-four hours, and the Tata Iron and Steel Works at Jamshedpur, in Singbhum, with three blast furnaces having a capacity of 900 tons of pig-iron per diem; the latter firm also possesses a steel works with seven furnaces capable of producing 17,500 tons of ingots per month, whilst extensions to both the blast-furnace plant and the steel works are in course of erection and a plate-mill has just been completed. A number of new works are being projected; the Indian Iron and Steel Co. is building blast furnaces for an output of 600 tons of pig-iron per diem at Hirapur, the Eastern Iron Co. is building blast furnaces close to the Jharia coalfield, whilst the United Steel Corporation of Asia is to establish works producing both iron and steel at Manoharpur; this last works intends to use coal from the new Karanpura coalfield. The Kirtyanand Iron and Steel Works, near Sitarampur, does not at present propose to make pig-iron, but is confining itself to the production of iron and steel castings. In connection with the Tata works a group of subsidiary concerns have been, and are being, formed at Jamshedpur to work up the iron and steel produced by these works; they comprise the Calcutta Monifieth Works (for producing machinery for jute manufacture), Enamelled Ironware, Ltd., the Tinplate Co. of India (which will supply the Burma Oil Co. and other Indian oil companies), the Agricultural Implements Co., the Indian Steel Wire Products, Ltd., the Enfield Co., and the Hume Pipe and Construction Co.

University and Educational Intelligence.

CAMBRIDGE.—The governing body of Emmanuel College offers to a research student commencing residence at the college in October next a studentship of the annual value of 150*l*., which shall be tenable for two years and renewable, but only in exceptional circumstances, for a third year. The studentship will be awarded at the beginning of October, and applications should be sent so as to reach the Master of Emmanuel (the Master's Lodge, Emmanuel College, Cambridge) not later than September 18.

The following grants from the Gordon-Wigan Fund are reported:—For plant-breeding experiments, 50*l*.; for museum cases, 35*l*.; for apparatus for studying marine organisms, 35*l*.; for the preparation of rock slices, 20*l*.; and for the preparation of sections of fossil plants, 10*l*.

The annual report of the General Board of Studies for the academic year 1920–21 refers to a distinct relief in the congestion in the scientific departments on account of the completion of new buildings. Fresh accommodation for chemistry and engineering has improved the position of affairs in those departments, and is easing it also in other departments. Several laboratories are faced with serious deficits on the year's working, and complaints are made of the effect of the 100 per cent. tax charged on certain things only procurable abroad. Valuable loans are announced of sound-ranging apparatus from the War Office and of radium from the Medical Research Council.

LONDON.—The three following courses of free public lectures are announced:—"The Crystallisation of Metals," by Col. N. T. Belaiew, at the Royal School of Mines, South Kensington, S.W.7, on Tuesdays, February 21 and 28 and March 7 and 14, at 5.30; "Some Recent Developments in Pharmacology," by Dr. H. H. Dale, at the London (Royal Free Hospital) School of Medicine for Women, Hunter Street, W.C.1, on Wednesdays, February 22 and March 1, 8, and 15, at 5; and "Certain Aspects of Fresh-water Algal Biology," by Prof. F. E. Fritch, at the East London College, on Wednesdays, February 15 and 22 and March 1, 8, 15, and 22, at 4.

OXFORD.—An examination for a natural science scholarship at Keble College is to be held on March 14. The annual value is 80*l*., with 20*l*. extra for laboratory fees. Applications should be made to Dr. Hatchett Jackson, Keble College, Oxford.

PROF. T. MATHER is retiring from the chair of electrical engineering in the City and Guilds (Engineering) College at the end of the present session after more than thirty-seven years' service in the college, first as assistant to the late Prof. Ayrton and then as his successor.

THE Association of Heads of Departments in Pure and Applied Science in Technical Institutions has forwarded a letter to the London County Council Education Committee directing attention to some anomalies arising from the revised scales of salaries following on the Burnham Report. It is pointed out that on the new scales the salaries of an assistant will rise automatically to a maximum which approximates to that of the head of a department, a state of affairs which gives an assistant little incentive to work for higher appointments involving additional responsibilities and qualifications.

A PAMPHLET entitled, "The Handicap," has been issued by the University of Glasgow as an appeal for support in an attempt to develop what may be termed the social, as opposed to the academic, side of university training in Glasgow. Benefactors in the past have contributed generously for the provision of professorships, scholarships, and laboratories—as much as 180,000*l*. has been given for such purposes during the past five years—but few have thought of providing for the well-being of the student outside the classroom. A notable exception was Dr. John M'Intyre, who, in 1889, presented a Students' Union to the university, but in spite of extensions, this building cannot accommodate more than 500 of the 3300 men students now in Glasgow. Another step towards the provision of a liberal education might be achieved by an extension of the hostel system in the hope of capturing some of the spirit of the older residential universities. At the present time hostel accommodation can be found for 40 men and 50 women, while 1016 men and 310 women students have to find such lodgings as are available in the city. It is for providing hostels and contributing in other ways to the welfare of the student that the appeal is being launched; grants and gifts amounting to some 40,000*l*. have already been promised, but it is considered that 150,000*l*. is really required. Contributions, which should be forwarded to Dr. A. E. Clapperton, secretary of the University Court, Glasgow, are therefore earnestly solicited, and it is hoped that a generous response will be forthcoming, particularly from the graduates and alumni of the university.

Calendar of Industrial Pioneers.

February 10, 1886. Edward Williams died.—First forge and mill master at the Dowlais Iron Works, South Wales, where under Menelaus he rolled the first steel rails from an ingot supplied by Bessemer, Williams was afterwards connected with the Cleveland iron trade at Middlesbrough, and for ten years was manager to Bölckow and Vaughan. He assisted in founding the Iron and Steel Institute, and in 1879–81 served as president.

February 10, 1912. Louis Delaunay Belleville died.—From the Ecole Polytechnique and the Ecole Navale Delaunay Belleville in 1867 entered the Belleville Engineering Works in Paris, and there brought out his well-known water-tube boiler for steamships. First fitted in French despatch vessels and cruisers it was afterwards extensively adopted in the French, Russian, and British Navies, allowing of the use of very high steam-pressures. Its use in our own Navy led to a vigorous controversy, and the Belleville boiler has since been superseded by others of simpler construction.

February 11, 1907. Léon Serpollet died.—A great French automobilist and a pioneer of the modern steam car, Serpollet brought out an improved form of flash boiler which in 1887 he used in a steam-propelled tri-car. Four years later he was the first to obtain authority to run his cars in the streets of Paris. His statue stands in the Rue Brunel.

February 12, 1874. Sir Francis Pettit Smith died.—The most prominent among the many inventors of screw propellers, Smith began life as a farmer. His patent was taken out in May, 1836, and during the next two years his screw was tried in the *Francis Smith* and the *Archimedes*. The success of the latter led Brunel to adopt screw propulsion for his trans-Atlantic liner, the *Great Britain*, while the Admiralty ordered the building of the H.M.S. *Rattler*, the first screw-driven man-o'-war. In 1845 the screw was adopted for all war-vessels. Smith remained Adviser to the Admiralty for a few years, and from 1860 until his death was curator of the Patent Office Museum.

February 13, 1824. Pierre Louis Guinaud died.—An improver of the manufacture of optical glass, Guinaud was a Swiss clockmaker. He was the first on the Continent to make flint-glass discs suitable for achromatic telescopes, and his success led to his co-operation for some years with Fraunhofer at Munich. Guinaud's methods were communicated by his son to Bontemps, who about 1848 was engaged by Chance, of Birmingham.

February 13, 1913. John Fritz died.—One of the great pioneers of the American steel industry, Fritz was born in Pennsylvania in 1822, his father being a native of Germany. He was intimately connected with the introduction of the Bessemer process into America, in 1857 erected the first three-high mill ever seen, and three years later became general superintendent of the Bethlehem Company. The John Fritz medal of the United Engineering Societies was founded in 1902.

February 14, 1831. Henry Maudslay died.—The founder of the firm of Maudslay, Sons, and Field, which during last century held a pre-eminent place among the builders of machinery for steamships, Maudslay, after working under Bramah, set up for himself in London, and in 1810 opened the works at Westminster Bridge Road. He patented a "table engine," built some of the earliest marine engines, constructed measuring machines, and improved machine tools. Many well-known mechanical engineers were trained in his shops. E. C. S.

Societies and Academies.

LONDON.

Royal Society, February 2.—Sir Charles Sherrington, president, in the chair.—C. **Shearer**: The oxidation processes of the echinoderm egg during fertilisation. The oxygen consumption and the carbon dioxide output of the eggs of the sea-urchin *E. microtuberculatus* during fertilisation have been measured by means of a special form of the Barcroft differential manometer. An immediate consumption of oxygen and a corresponding output of carbon dioxide take place on the sperm being added to the eggs. At the end of one minute this increase is equivalent to a rise in the metabolic rate of the egg of more than 8000 per cent. Sections of fixed material preserved during different intervals of the process of fertilisation show that this is brought about by the contact of the sperm with the external surface of the egg-membrane. The fusion of the male and female pronuclei in the later phases of fertilisation is without any influence on the curve of the oxygen consumption. The dipeptide glutathione is present in both ripe germ-cells of the sea-urchin *E. miliaris*, but one minute after fertilisation it is found in much greater quantity in the egg in reduced form, and evidence shows that it plays a very important, if not the chief, part in the oxidation processes taking place.—J. **Schmidt**: The breeding-places of the eel. The common or fresh-water eel (*Anguilla anguilla* or *A. vulgaris*) of Europe has only one breeding area, as determined by the distribution of the larvæ, situated in the western Atlantic, south-east of Bermuda. The larvæ are pelagic, and are carried to the east and north-east by the Atlantic current; their growth and the metamorphosis into the "elver," or young eel, are described; the elvers are three years old. The breeding area of the American eel (*A. chrysypa*) is south-west of that of the European eel, but overlaps it; in the American eel growth of the larvæ is much more rapid than in the European species, and the elvers are only one year old. This explains why the European eel is not found in American rivers or the American eel in Europe; if larvæ of the American eel are carried eastwards, the metamorphosis takes place in the middle of the Atlantic; if larvæ of the European eel go north or north-west, they reach the American coast two years before the metamorphosis is due.—J. **Gray**: The mechanism of ciliary movement. Pts. 1 and 2. The rate of beat of the cilia on the gills of *Olytilus edulis* can be controlled by adjusting the hydrogen-ion concentration of the cell interior. The amplitude of the beat can be controlled by an alteration in the osmotic pressure of the external medium. The cilium is essentially a bundle of elastic fibres the tension of which varies during the different phases of the beat. The activity of cilia and muscle-cells depends on similar conditions and mechanisms. The normal properties of the cell-membrane are maintained only in the presence of divalent cations. Ciliated cells are permeable to monovalent cations, but not to anions. Ciliary activity may persist when the normal semi-permeable properties of the cell-wall have been destroyed—J. S. **Huxley** and L. T. **Hogben**: Experiments on amphibian metamorphosis and pigment responses in relation to internal secretions. Salamandra and Triton larvæ may be metamorphosed by immersion in a dilute solution of iodine. Metamorphosis is retarded by low temperature; high temperature at first causes increased growth of the gills. Sexually mature Axolotls can be made to undergo rapid metamorphosis by means of a thyroid diet. Metamorphosis is accompanied by exophthalmos, apparently in all Amphibia. Iodine free of organic combination, and fresh glandular substance of the prostate and pituitary anterior lobe, are without effect on the metamorphosis of the Axolotl. Pituitary feeding produces a marked temporary dilatation, followed by excessive contraction of the dermal melanophores in albino Axolotls. Adrenal medulla extract produces, temporarily, complete contraction of the dermal melanophores in the Axolotl. Pineal administration rapidly causes a striking transient contraction of the dermal melanophores in frog tadpoles, but has no effect on the melanophores of the Axolotl. Seven months' thyroid feeding was not accompanied by any noteworthy somatic changes in Necterus.

Royal Meteorological Society, January 18.—Mr. R. H. Hooker, president, in the chair.—R. H. **Hooker**: The weather and the crops in eastern England, 1885–1921. The objects of the inquiry were: (1) To determine by the method of correlation, on the basis of the thirty-five years 1885–1919, which were the critical periods in the growth of farm crops; (2) to ascertain how far each such period was responsible for the actual crops harvested in each year. Wheat is most seriously affected by wet weather at sowing in autumn and winter, while warmth in winter is beneficial. The chief requirement of barley is a cool, dry early summer, whereas for oats the same period should be wet and cool. Turnips need rain about June, but cool weather is even more important; for hay the fundamental necessity is rain in the late spring. A cool summer is more important than rainfall for almost all crops except hay, and even that is the better for cool weather. The requirements of potatoes are practically the opposite of all other crops. For quality of seed, absence of rain, and in some cases warmth, is desirable. One feature strongly emerges, viz. that so far as regards bulk of corn the east of England is too wet (except for oats and beans) and too warm. The worst years, particularly 1893 and 1911, were due to hot, dry summers, and the same feature was the cause of the generally bad crops of 1921, though wheat, which withstands heat and drought well, was a record. As a type of a good all-round year 1902 was selected; it was characterised by prolonged cool weather throughout the spring and summer, accompanied by rain until June, and followed by dry weather. In the east of England 1920 had a cool summer, only partly spoilt by rain in July, and the resultant crops were mostly good. The fifteen years 1895–1910 were mostly a period of good crops, but in the last seven or eight years there have been a succession of very unfavourable weather conditions, notable chiefly for dry, warm springs.

Geological Society, January 18.—Mr. R. D. Oldham, president, in the chair.—A. C. **Seward** and R. E. **Holttum**: Jurassic plants from Ceylon. The plant-impressions are from a shale resting upon Archæan rocks at Tabbowa, in the North-Western Province of Ceylon. These are the first fossil plants recorded from the island. The plant-bearing beds coincide, both in the composition of the flora and in their relation to the older igneous rocks, with those of Madras.—F. S. **Wallis**: The Carboniferous Limestone (Avonian) of Broadfield Down (Somerset). Lithologically and palæontologically the area holds an intermediate position, and forms a link, between the developments of the Bristol and the Mendip districts. A well-marked faunal assemblage is described from the top of S_1. It constitutes a very useful field determination of the datum-line between the S_1 and S_2 sub-zones. *Pustula elegans* (M'Coy) from the S_1 sub-zone and the sub-zones Z_1 and D_1 are recorded for the first time from this area.

Linnean Society, January 19.—Dr. A. Smith Woodward, president, in the chair.—A. B. **Rendle**: Specimen of wood of *Orites excelsa*, R. Br. (family Proteaceæ), one of the Australian silky oaks. The tree, which is a native of northern New South Wales and Queensland, is of unique interest from the deposits of aluminium succinate which occur in cavities of the wood. Aluminium is very rarely found in flowering plants, and only in small traces; but *Orites excelsa* absorbs alumina from the soil in large quantities, as shown by analysis of the ash. Occasionally the amount taken up is excessive, in which case the excess is deposited in cavities as a basic aluminium succinate.—E. Marion **Delf** and Miss M. M. **Michell**: Studies in *Macrocystis pyrifera*. After describing the distribution of the alga, the authors reviewed recent accounts of it. The fertile fronds are completely submerged, smooth, dichotomously branched, and usually borne on special shoots. They bear sori on both sides of the frond. Exceptional cases were described of discontinuous sori occurring in the grooves of fronds with wrinkled surface and borne on the long swimming shoots, and usually without a swim bladder at the base. The zoospores do not appear to have been previously described. Material brought from the shore in the morning and examined in the laboratory in the evening showed swarming zoospores, the next morning swimming actively, and more slowly. The authors consider that the species occurring at the Cape is *Macrocystis angustifolia*, Bory, from its rhizome-like attachments.—J. L. Chaworth **Musters**: The flora of Jan Mayen Island. The flora of Jan Mayen may be divided into four main groups. The floras of the seashore, of the bird-cliffs, of sheltered places in the "tundra," and the mountain flora. The most luxuriant flora, which consists of Taraxacum or Oxyria, grows either under the bird-cliffs or in places where tuff has been re-assorted by water. The limit of flowering plants seems to be about 3000 ft. The total phanerogamic vegetation consists of about forty-three species, all of which are common to both Norway and East Greenland. The origin of the flora presents a very complicated problem. Seeds have probably been brought there on the feet of wading birds which migrate to and from their breeding-grounds in East Greenland. It is highly improbable that Jan Mayen has ever been connected with either Iceland or Greenland. Many plants have probably reached Jan Mayen during very recent years.

PARIS.

Academy of Sciences, January 23.—M. Emile Bertin in the chair.—The president announced the death of M. Camille Jordan, member of the Academy.—D. **Riabouchinski**: Some considerations on the form of the solid and the kinetic energy of the fluid which surrounds it.—A. **Perot**: The variation in the wave-length of the telluric lines. From measurements made in 1914 and in 1920–21 on the atmospheric lines of the B group the wave-length has been found to vary with the height of the sun above the horizon, nearly proportional to the sine of the angle. The hypothesis that the variation of the wave-length as measured was caused by an unsymmetrical widening of the line has been examined and rejected as insufficient to explain the observed facts.—H. **Colin** and Mlle. A. **Chaudun**: The law of action of sucrase: the velocity of hydrolysis and the reaction of the medium. It is well known that the activity of the hydrolysing diastases, especially sucrase, depends on the acidity of the medium. Results are given of the velocities of inversion of cane-sugar by sucrase in solutions of varying alkalinity and acidity. The velocity of inversion attains a maximum for a given acidity, and then falls off with further additions of acid. The addition of acid corresponds with a diminution of the quantity of the enzyme taking part in the reaction. The apparent immobilisation of a part of the diastase is most readily explained by the hypothesis of the formation of a sugar and enzyme complex of a physical nature.—C. F. **Muttelet**: A new method for the detection of coco-fat in butter. The cholesterol and phytosterol are precipitated by digitonin and converted into acetates. The cholesterol acetate melts at 113·6° to 114·2°, the phytosterol acetate at 125°, and mixtures at intermediate temperatures.—P. **Lemoine** and R. **Abrard**: The existence of the Upper Cretaceous in the central cavity of the Channel from the dredgings of the *Pourquoi Pas?* A map of the Channel is given showing the points at which soundings have been taken and distinguishing between spots where Cretaceous deposits have been obtained and spots where the specimens of rocks do not belong to that period. The deposits from the bottom of the central cavity (*fosse centrale*) clearly belonged to the Cretaceous period.—L. **Dussault**: The geology of the province of Sam Neua (Eastern Haut Laos).—R. **Bourret**: The massifs of the north-east of Tonkin.—P. **Russo**: The structure of the Trias of the regions of Meknés, Innaouen (northern Morocco).—S. **Stefanescu**: The practical and phylogenetic importance of the T_n of the molars of mastodons and elephants.—A. **Allix**: Observations on relief sculpture by ice. An account of the direct study of rock erosion by ice in the large crevasses of Mont Pelvoux. The views of W. D. Johnson and of B. Stracey on rock erosion by ice action are confirmed.—G. **Dubois**: Modifications of the seashore at Sangatte resulting from the storms of December, 1921.—L. **Besson** and H. **Dutheil**: The displacement of rises and falls of the barometer and the direction of movement of cirrus clouds.—R. **Combes**: The formation of anthocyanic pigments. A criticism of recent communications on this subject by Kurt Noack and St. Jonesco. The colouring matters obtained by these authors are regarded as derived from phlobatannins, and not from γ-pyronic pigments: a red coloration with alkalis is not sufficient proof of the presence of an anthocyanic pigment.—G. **Hamel**: The algæ of Rockall. In June, 1921, the Island of Rockall, 240 miles north-west of Ireland, was visited by the *Pourquoi Pas?*, and M. Le Conte and three sailors effected a landing and secured specimens of the algæ. The only brown alga was *Alaria esculenta*: neither Fucus nor Laminaria were noted.—E. **Chemin**: The parasitism of *Sphacelaria bipinnata*.—W. **Koskowski**: The action of histamine on the secretion of the gastric juice in pigeons. Histamine is not destroyed in the blood, and is not transformed in the blood into a substance stimulating the gastric secretion, but it undergoes this transformation in other tissues, principally in the skin.—C. **Levaditi** and S. **Nicolau**: A pure cerebral vaccine: its virulence for man. Vaccine virus, cultivated in the brain of the rabbit for eight months (110 passages), retains its affinity for the human skin. It produces normal vaccination without any complications, and has the advantage over ordinary vaccine of being absolutely pure without the addition of antiseptics.—A. **Donatien** and R. **Bosselut**: Acute contagious encephalitis of the ox. In 1921 a contagious disease caused the death of nine cattle in the neighbourhood of Algiers. Some of the symptoms suggested rabies, but this was proved not to be the case. The disease was transmissible to cattle, rabbits, and guinea-pigs, and was proved to be neither rabies nor Aujesky's disease. It appears to be new, and is being further studied.

Official Publications Received.

Jamaica. Annual Report of the Department of Agriculture for the Year ended 31st December, 1920. Pp. 29. (Kingston, Jamaica: Department of Agriculture.)

Straits Settlements. Annual Report on the Raffles Museum and Library for the Year 1920. By Major J. C. Moulton. Pp. ii+21. (Singapore.)

Diary of Societies.

THURSDAY, FEBRUARY 9.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Napier Shaw: Droughts and Floods (2).

HARVEIAN SOCIETY OF LONDON (at St. Mary's Hospital, Paddington), at 4.30.—Clinical Meeting.

ROYAL SOCIETY, at 4.30.—Sir J. A. Ewing: The Atomic Process in Ferromagnetic Induction.—Prof. J. W. Nicholson: Problems relating to a Thin Plate Annulus.—Prof. T. H. Havelock: The Effect of Shallow Water on Wave Resistance.—R. H. Fowler and S. N. H. Lock: The Aerodynamics of a Spinning Shell. Part II.—F. P. Pidduck: The Kinetic Theory of a Special Type of Rigid Molecule.—J. E. Jones: The Velocity Distribution Function and the Stresses in a Non-uniform Rarefied Monatomic Gas.—H. Bateman: The Numerical Solution of Linear Integral Equations.

LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5.—H. Hilton: Conics on the Pseudo-sphere.—W. F. D. MacMahon: The Design of Repeating Patterns in Euclidean Space of 3 Dimensions.—G. H. Hardy and J. E. Littlewood: Dirichlet's Series with a Barrier of Singularities.

INSTITUTION OF CIVIL ENGINEERS (Students' Meeting), at 6.—E. J. Kingston-McCloughry: The Design of Modern Water-turbines.

OPTICAL SOCIETY (at Imperial College of Science and Technology), at 7.30.—Annual General Meeting.—F. W. Preston: The Structure of Abraded Glass Surfaces.—A. J. Dalladay and F. Twyman: The Stress Conditions Surrounding a Diamond Cut in Glass.—Lt.-Col. J. W. Gifford: A Supplementary Note on Achromatic One-Radius Doublet Eyepieces.—F. Twyman and A. J. Dalladay: Change in Refractive Index at the Surfaces of Glass Melts.

CHEMICAL SOCIETY (at Institution of Mechanical Engineers), at 8.—Sir Ernest Rutherford: Artificial Disintegration of Elements.

INSTITUTE OF METALS (London Section) (at Sir John Cass Technical Institute, Jewry Street, E.C.3), at 8.—R. T. Rolfe: Gun-metal.

SOCIETY OF ANTIQUARIES, at 8.30.

ROYAL SOCIETY OF MEDICINE (Neurology Section), at 8.30.—Dr. F. Buzzard: Some Varieties of Traumatic and Toxic Ulnar Neuritis.

FRIDAY, FEBRUARY 10.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.—Annual General Meeting.—Dr. E. A. Owen and Bertha Naylor: The Measurement of the Radium Content of Sealed Metal Tubes.—Sir William Bragg: The Crystal Structure of Ice.—Dr. K. Grant: A Method of Exciting Vibrations in Plates, Membranes, etc., Based on Bernoulli's Principle.

ROYAL ASTRONOMICAL SOCIETY, at 5.—Anniversary Meeting.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. A. C. Pannett: Hydronephrosis (Hunterian Lecture).

KING'S COLLEGE ENGINEERING SOCIETY (Anniversary Meeting) (at Institution of Civil Engineers), at 5.30.—F. W. Macaulay: Water Engineering.

ROYAL SOCIETY OF MEDICINE (Clinical Section), at 5.30.

MALACOLOGICAL SOCIETY (at Linnean Society), at 8.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—Questions and General Discussion.

ROYAL SOCIETY OF MEDICINE (Ophthalmology Section), at 8.30.—Miss I. C. Mann: The Morphology of Certain Developmental Structures associated with the Upper End of the Choroidal Fissure.—Dr. H. J. May and F. A. Williamson-Noble: Three Cases of Choroidal Sarcoma, with Notes on the Microscopic Appearances.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. W. D. Halliburton: The Teeth of the Nation.

MONDAY, FEBRUARY 13.

ROYAL GEOGRAPHICAL SOCIETY (at Lowther Lodge, Kensington Gore), at 5.—Lt.-Col. M. N. MacLeod and A. R. Hinks: Stereographic Survey.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. V. Z. Cope: The Nerve-supply of the Parietal Peritoneum and the Subperitoneal Tissues, with Remarks on its Clinical Significance (Arris and Gale Lecture).

ROYAL SOCIETY OF MEDICINE (War Section), at 5.30.—Lieut.-Colonel C. R. Sylvester-Bradley: Stature in relation to Physical Fitness.

MEDICAL SOCIETY OF LONDON (at 11 Chandos Street, W.1), at 8.30.—Prof. H. Hartmann: Inflammatory Strictures of the Rectum.

TUESDAY, FEBRUARY 14.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. H. H. Turner: Variable Stars (3); Our Sun.

ROYAL SOCIETY OF MEDICINE (Therapeutics and Pharmacology Section), at 4.30.—Dr. H. H. Dale and Major C. E. White: An Experimental Method of Determining the Therapeutic Efficiency of "914" Preparations.—Dr. R. L. Mackenzie Wallis: Tests for Hepatic Insufficiency after Arseno-benzol Treatment.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—Prof. The Svedberg: (1) The Relation between Sensitiveness and Size of Grain in Photographic Emulsions (Part 2); (2) The Reducibility of the Individual Halide Grains in a Photographic Emulsion.—Dr. S. E. Sheppard and A. P. H. Trivelli: Note on Prof. Svedberg's Method of Grain Analysis of Photographic Emulsions.—K. C. D. Hickman: An Optical Method of Testing Washing Devices.

QUEKETT MICROSCOPICAL CLUB, at 7.30 (Annual General Meeting).—Dr. A. B. Rendle: Presidential Address.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Prof. G. Elliot Smith: The Brain of Rhodesian Man.

ROYAL SOCIETY OF MEDICINE (Psychiatry Section), at 8.30.—Dr. Helen Boyle: The Ideal Clinic for the Treatment of Nervous and Borderland Cases.

WEDNESDAY, FEBRUARY 15.

ROYAL SOCIETY OF MEDICINE (History of Medicine Section), at 5.—Dr. C. Singer: Recently Discovered Inscriptions recording Ancient Cures.—Dr. F. G. Crookshank: The "Trousse-galland."—Dr. H. D. Davis: A Very Early Illustration of a Skin Disease.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Dr. F. W. Edridge-Green: New Researches in Colour-vision (Arris and Gale Lecture).

ROYAL SOCIETY OF ARTS, at 8.—Cloudesley Brereton: The Necessity of Speech Training, and the Need of a National Conservatoire.

ROYAL MICROSCOPICAL SOCIETY, at 8.—Prof. B. L. Bhatia: Freshwater Ciliate Protozoa of India.—A. L. Booth: The Microstructure of Coal from an Industrial Standpoint.—Capt. F. Oppenheimer: A Portable Microscope

THURSDAY, FEBRUARY 16.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. A. G. Perkin: Dyeing: Ancient and Modern (1).

ROYAL SOCIETY, at 4.30.—*Probable Papers*.—Prof. L. Hill, D. H. Ash, and J. A. Campbell: The Heating and Cooling of the Body by Local Application of Heat and Cold.—Prof. J. B. Cohen, C. H. Browning, R. Gaunt, and R. Gulbransen: Relationships between Antiseptic Action and Chemical Constitution, with Special Reference to Compounds of the Pyridine, Quinoline, Acridine, and Phenazene Series.—D. T. Harris: Active Hyperæmia. —B. B. Sarkar: The Depressor Nerve of the Rabbit.—Prof. A. Lipschütz, Dr. B. Ottow, C. Wagner, and F. Bormann: The Hypertrophy of the Interstitial Cells in the Testicle of the Guinea Pig under Different Experimental Conditions.

LINNEAN SOCIETY OF LONDON, at 5.

ROYAL SOCIETY OF MEDICINE (Dermatology Section), at 5.

ROYAL METEOROLOGICAL SOCIETY, at 5.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.30.—Sqdr.-Ldr. C. F. A. Portal: Methods of Instruction in Aeroplane Flying.

INSTITUTION OF MINING AND METALLURGY (at Geological Society of London), at 5.30.—J. M. Bell: The Occurrence of Silver Ores in South Lorrain, Ontario, Canada.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—F. P. Whitaker: Rotary Converters, with Special Reference to Railway Electrification.

CHEMICAL SOCIETY, at 8.—A. Lapworth: A Theoretical Derivation of the Principle of Induced Alternate Polarities.—W. O. Kermack and R. Robinson: An Explanation of the Property of Induced Polarity of Atoms and an Interpretation of the Theory of Partial Valencies on an Electronic Basis.

SOCIETY FOR CONSTRUCTIVE BIRTH CONTROL AND RACIAL PROGRESS (at Essex Hall, Essex Street, W.C.2), at 8.—E. B. Turner: Sex Relationships.

FRIDAY, FEBRUARY 17.

GEOLOGICAL SOCIETY OF LONDON (Annual General Meeting), at 3.—Presidential Address.

ROYAL SOCIETY OF MEDICINE (Otology Section), at 5.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. Swale Vincent: A Critical Examination of Current Views on Internal Secretion (Arris and Gale Lecture).

INSTITUTION OF MECHANICAL ENGINEERS (Annual General Meeting), at 6.—A. T. Wall: Electric Welding applied to Steel Construction, with Special Reference to Ships.

JUNIOR INSTITUTION OF ENGINEERS (at Caxton Hall), at 8.—W. J. Leaton: Water Purification for Boiler Feed Purposes.

SOCIÉTÉ INTERNATIONALE DE PHILOLOGIE, SCIENCES ET BEAUX-ARTS (Celtic Section) (at 8 Taviton Street, W.C.1), at 8.—Dr. W. J. E. Scott: The Mines of El Dorado: an Historical Account of the Maritime Trade of Spain with Ireland, 2000 to 700 B.C. (2).

ROYAL SOCIETY OF MEDICINE (Electro-therapeutics Section), at 8.30. —Dr. G. W. C. Kaye: Radiology and Physics (Mackenzie-Davidson Memorial Lecture).

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. D. S. M. Watson: History of the Mammalian Ear.

SATURDAY, FEBRUARY 18.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. E. A. Gardner: Masterpieces of Greek Sculpture (1).

PUBLIC LECTURES.

(*A number in brackets indicates the number of a lecture in a series.*)

THURSDAY, FEBRUARY 9.

UNIVERSITY COLLEGE, at 5.15.—Prof. J. E. G. de Montmorency: Welsh and Irish Tribal Customs (1).

KING'S COLLEGE, at 5.30.—Dr. O. Faber: Reinforced Concrete (4). —M. Beza: Nereids in Roumanian Folk-lore.

TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES (at the Mary Ward Settlement, Tavistock Place, W.C.1), at 5.30.—Dr. H. Crichton Miller: The New Psychology and its Bearing on Education (3).

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN (Leicester Square, W.C.2), at 6.—Dr. W. Griffith: The Skin Eruptions of Syphilis (Chesterfield Lecture).

FRIDAY, FEBRUARY 10.

METEOROLOGICAL OFFICE (South Kensington), at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (4).

SATURDAY, FEBRUARY 11.

LONDON DAY TRAINING COLLEGE, at 11 a.m.—Prof. J. Adams: The School Class (4).

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Miss M. A. Murray: The Domestic Life of the Ancient Egyptians.

MONDAY, FEBRUARY 13.

UNIVERSITY COLLEGE, at 5.15.—A. G. R. Foulerton: Administrative Measures for the Improvement of the Public Health.

CITY OF LONDON (BOYS') SCHOOL (Victoria Embankment), at 5.30.—Miss Rosa Bassett: The Dalton Plan of Self-education (2).

KING'S COLLEGE, at 5.30.—Dr. J. S. Steppat: Recent Developments in German Education and Student Life (4).—Prof. C. L. Fortescue: Wireless Transmitting Valves (4).

TUESDAY, FEBRUARY 14.

LONDON SCHOOL OF ECONOMICS AND POLITICAL SCIENCE, at 6.—Sir Josiah C. Stamp: The Administrative Factor in Government (1).

WEDNESDAY, FEBRUARY 15.

EAST LONDON COLLEGE, at 4.—Prof. F. E. Fritch: Certain Aspects of Freshwater Algal Biology (1).

SCHOOL OF ORIENTAL STUDIES, at 5.—Dr. L. D. Barnett: The Jains.

HORNIMAN MUSEUM (Forest Hill), at 6.—W. W. Skeat: The Living Past in Britain (4).

UNIVERSITY COLLEGE, at 8.—The Current Work of the Biometric and Eugenics Laboratories (1).—Prof. Karl Pearson: Side-lights on the Evolution of Man: From the Knee-joint.

THURSDAY, FEBRUARY 16.

UNIVERSITY COLLEGE, at 5.15.—Prof. J. E. G. de Montmorency: Welsh and Irish Tribal Customs (2).

KING'S COLLEGE, at 5.30.—Dr. O. Faber: Reinforced Concrete (5).—M Beza: Nereids in Roumanian Folklore (2).

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN (Leicester Square, W.C.2), at 6.—Dr. W. K. Sibley: Seborrhœa and Psoriasis (Chesterfield Lecture).

FRIDAY, FEBRUARY 17.

METEOROLOGICAL OFFICE (South Kensington), at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (5).

KING'S COLLEGE, at 5.—Prof. R. Robinson: Orientation and Conjugation in Organic Chemistry from the Standpoint of the Theories of Partial Valency and of Latent Polarity of Atoms (2).

UNIVERSITY COLLEGE, at 5.—Prof. G. Elliot Smith: The Evolution of Man (2).

TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES (at Mary Ward Settlement, Tavistock Place, W.C.1), at 5.30.—Dr. H. Crichton Miller: The New Psychology and its Bearing on Education (4).

SATURDAY, FEBRUARY 18.

ROYAL SOCIETY OF ARTS, at 10.30 a.m.—Prof. J. A. Thomson: The Migration of Birds (Lectures for Teachers).

LONDON DAY TRAINING COLLEGE, at 11 a.m.—Prof. J. Adams: The School Class (5).

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Dr. E. Marion Delf: A Botanist in South Africa.

Research and Education in the Geddes Report.

THE first and second sections of the interim Report of the Committee on National Expenditure, presided over by Sir Eric Geddes, were published on February 10 (Cmd. 1581, 4*s.* net; Cmd. 1582, 3*s.* net), and the particulars of expenditure and proposed economies in the various supply services are receiving much public attention. Throughout the Report reductions are recommended in expenditure on education and research, on the general principle that the reduced resources of the nation at the present time make all possible economies essential. Thus we have such sweeps of the axe as:—Research for Army purposes to be reduced from 625,000*l.* to 312,000*l.*; Naval scientific services (400,000*l.*) to one-half; aviation research from 1,500,000*l.* to 500,000*l.*

The attitude of the Committee towards education and research, which is disclosed in the supercut of 18,000,000*l.* in the Board of Education Vote, is dominated by the narrow commercial view of goods to be delivered for money expended. The contemptible sum doled out to agricultural education and research before the war, when compared with the amounts spent in foreign countries—notably in the United States—was notorious. During the post-war reconstruction, as we noticed at the time, important administrative reforms were introduced, directed mainly to the future recruitment of the best scientific talent, which justified the hope that this country would regain the pre-eminence in agricultural science which it once enjoyed. In England and Wales the cut proposed involves a drop from 365,000*l.* to 250,000*l.*; in Scotland from 112,000*l.* to 62,000*l.* In the former case the provision for research is reduced from 109,000*l.* to 75,000*l.*, and if carried out literally will involve the dismissal of staff holding pensionable posts, and, possibly, the abandonment of land and buildings specially equipped for scientific purposes.

In some respects these recommendations are as astonishing as any contained in the report; for under the provisions of the Corn Production (Repeal) Act of 1921—passed, be it noted, after the economy campaign was begun—a sum of 1,000,000*l.* was voted for *additional* expenditure on agricultural education and research. It would almost seem that the Committee, which professes to exclude this sum from consideration, has deliberately aimed at opening an abyss into which this million shall disappear. For it should be noted that, in terms, the cut includes the Development Fund, and as that fund is almost on its last legs (the balance now in hand will little more than suffice for one year's normal requirements), the operation suggested is one which, in the vernacular of some members of the Committee, is known as "taking the breeks off a Highland man." Even if the Development Commissioners, in the exercise of the discretion which the Committee leaves them, use the Corn Production Fund to fill the gap created in the old fund, the remedy would be temporary only, and, in any event, would create the anomaly of giving preferential treatment to agricultural education and research. What does business acumen think of adding a top story to a building and at the same time destroying the ground floor?

The activities of the Forestry Commission are threatened with extinction by the Report, which recommends that the scheme of afforestation by the State shall be discontinued, that the vote of 275,000*l.* for the ensuing financial year shall not be allowed, and that steps should be taken to cancel the remaining 2,822,000*l.* of the 3,500,000*l.* authorised for the decade following 1919, the date of the Forestry Act. In the Report no complaint is made about the work or the administration of the Forestry Commission. It simply says: "We recognise the enthusiasm and public spirit of the Commissioners, but in the present state of the country's finance we cannot recommend that this expenditure—which will always show a heavy loss, and which cannot reach full fruition for something like eighty years—should be continued."

Foresters believe that afforestation will show a

profit rather than a loss, but this is not the real issue. The Committee ignores the main argument for afforestation in Great Britain—namely, national security. This country, without an adequate supply of timber within its own shores, is exposed to great peril in time of war. During the Great War the expenditure incurred on foreign timber was 200,000,000*l*. more than if the prices of 1913 had prevailed, and the enormous cargo space needed for such a bulky import endangered our food supply from overseas, and at one time brought us to the brink of starvation. The insurance against such a calamity—350,000*l*. annually—is a trifle. No heed is given in the Report to the cheapness of the afforestation, which is carried out in many cases on leased land, no capital expenditure for land purchase being required. The Government in November last actually allotted to the Forestry Commission an extra 250,000*l*. out of the Unemployment Fund, which puts 5000 idle men at work in replanting the woodland areas felled during the war. The Forestry Commission has acquired large areas of land; it has entered into many leases and contracts; it owns millions of seedling trees ready for transplanting; it has established schools for woodmen and instituted research. It is evident that the "scrapping" of such an efficient service would result in an immediate great loss of money and be a waste rather than an economy.

The section of the Report dealing with education is of special interest in so far as it carries to extreme limits that separation between the finance of education and education proper which is the characteristic tendency of the business man of to-day when he considers such matters. The obvious danger of this tendency is that finance comes to be looked upon as the only thing which matters in education, and this danger is particularly exemplified in the Report.

It should be clearly understood that the Report is the product of business men accustomed to deal with affairs on a large scale, especially in respect of railways and shipping. They are men who have made their reputation mainly in transport services, but apparently know little or nothing about education from the inside, and, so far as we are aware, make no claim to any expert or special knowledge of the subject. For example, their recommendation that children should not be taken into State-aided schools until they have reached the age of six is based, as they are careful to explain, upon the opinion of others. Obviously they do not pretend to understand the educational bearing of the question, and wisely throw the onus upon others whom, still more wisely, they carefully omit to name.

All the same, we naturally expect them to show a masterly grasp of finance, and we are not disappointed. They handle figures running into hundreds of millions with an ease and freedom and a dexterity which cannot but provoke our admiration. Occasionally—but only occasionally—they lose their balance and their business acumen, and, in their desire to cut down the Estimates, suggest proposals which would actually increase the public cost of education. A flagrant instance of this is their recommendation to withdraw Parliamentary grants from a certain type of secondary school, regardless of the fact that local education authorities have helped to support such schools "because it was cheaper for them to do so than to set up secondary schools of their own." Even a committee of business men can be too solicitous of the Exchequer!

In the main, then, as regards education, the Report deals with finance, and only incidentally or by implication with education *per se*. The task of the Committee is to cut down the Estimates, and the net result of the proposals, if adopted, would be, as we have said, to reduce the education grant by 18,000,000*l*. This is to be achieved by reducing the salaries of teachers and making them contribute 5 per cent. of their reduced salaries for superannuation purposes; by increasing the number of pupils for each teacher in elementary schools; by limiting the number of those granted free secondary education; by a reduction in the number of scholarships; by discontinuing the State scheme of scholarships at the universities; and by cutting down the annual grant to the universities. In addition, the Committee recommends the abolition of the percentage grant system, which it characterises as a money-spending device. "The vice of the percentage grant system," so runs the Report, "is that the local authority, which alone can really practise economy in these services, loses much of its incentive to reduce expenditure, especially when the larger proportion is paid by the taxpayer through the Exchequer." As a substitute, fixed grants or grants based on some definite unit are recommended. In this way the Committee hopes that the local education authorities will be discouraged from spending money on education, and is not ashamed to avow this. No charge of wanton waste or of useless expenditure is laid against local authorities.

The danger of dissociating the finance of educa-

tion from education is obvious when a Committee can make such drastic proposals without giving some assurance that the recommendations would not reduce national efficiency. It may be easy to deal with educational finance on the shipping and railway plan, but it is not possible to deal with education on the same plan. Education means something bigger than business accountancy. It means knowledge, vision, a sense of humanity, and some recognition of the spiritual aspects of civilisation.

Apart from considerations such as these, Sir Eric Geddes and his Committee have made one or two cardinal blunders. Even as business men they have shown themselves singularly short-sighted. To deprive the universities of 300,000*l.* a year may relieve the income tax of one-twentieth of a penny for the moment, but in the long run the effect will be disastrous. This is just the sort of policy which cripples the nation in the higher reaches of commerce and industry. Similarly, as business men they ought to know that, in a profession such as teaching, in which the financial rewards at the best are meagre compared with those in other walks of life, there is a salary limit below which it is impossible to recruit the profession with men. During the past twenty years the statistics show a serious relative decline in the number of men teachers. If the proposals of the Committee are adopted, the decline will be still more serious. In another respect the Committee seems to us to have gone astray. Its proper function was not to show how to reduce the quantum and efficiency of education, but rather to demonstrate how these could be maintained, if at all possible, at a lower cost to the country, and it has failed to do this.

On the other hand, we are not disposed to maintain that our educational system is flawless, or that it cannot be administered with greater efficiency and at less cost. Undoubtedly there could be a saving all round, and one might very reasonably begin with the Board of Education itself, which, to a large extent, seems to have escaped the financial criticisms of the Committee. Nor are we disposed to take too seriously the Committee's observations regarding the impotence of this Board, which has hitherto shown no great anxiety to limit its own powers.

Fortunately, however, another and wider tribunal will decide upon the larger questions of policy involved in the Report, and, in the light of knowledge and criticism, determine the value or otherwise of the recommendations. There is little doubt as to the verdict; most assuredly these recommendations will not be endorsed in their entirety by Parliament or by the more thoughtful section of the community outside Parliament. National efficiency and progress must be the first consideration, and any action which would lower the standard of either of these may be immediate retrenchment, but would not be economy.

The Supply of Gaseous Fuel.

Modern Gasworks Practice. By Alwyne Meade. Second edition, entirely rewritten and greatly enlarged. Pp. xii + 815. (London: Benn Bros., Ltd., 1921.) 55*s*.

AMONG the many truths brought home to the country by the two national struggles in which it has recently been engaged, the importance of the coal distillation industry stands out conspicuously. The rational treatment of coking coal by such means before its combustion (a process which has been carried out in our chief cities for more than a century) provided during the world war enormous quantities of material for belligerent use. It was no less effective as an instrument of social peace during the coal war, for our town-dwellers of all classes throughout the length and breadth of the land satisfied much of their requirements for the cooking of food, and in most cases for lighting their homes, by a mixture consisting chiefly of the lightest of the common gases, hydrogen, fortified with carbon in various combinations, produced in the main by the direct or indirect gasification of coal. Its centrally organised provision has now become a necessity of modern life in all our towns and most of our villages, just as are those for the supply of water and electric energy, and for the disposal of sewage. These have been almost wholly developed as engineering problems, though in the three latter cases the mathematician and the chemist, the physicist and the bacteriologist, have from time to time laid down certain principles to be followed. It will not, however, be denied that the finger of science was too often disregarded in working out the processes ancillary to the production of town's gas, and it is interesting, therefore, to observe that a change of this attitude is indicated in the pages of this latest work upon the subject.

In this exhaustive compilation, profusely illustrated with diagrams and working drawings, the technologist's debt to science, whether in the compounding of refractories or their usage, the composition of the coal or of its treatment in the cold

or by heat with the view of obtaining the highest yields in products, is fittingly acknowledged. The general public is becoming aware that there is in progress a complete revolution in the computation of gas charges, arising out of Sir George Beilby's suggestion that thermal value be substituted for mere volume as their basis (a therm of 100,000 B.Th.U. constituting the standard). A curious commentary upon these proposals is that they were carried only in the face of considerable opposition on the part of the administrators of gas undertakings. In Mr. Meade, however, they find a doughty champion whose support for them in the volume under review proclaims a teaching as sound as his practice is progressive. It is, however, unlikely that his doubt as to the intention of the gas referees substantially to prescribe the installation of continuously recording calorimeters is well founded. This body of men of science (among whom is Prof. C. V. Boys), now entrusted with the regulation of gas supplies, would probably be the last to admit that the design of such instruments offers insuperable obstacles, or that their use is not at least as necessary as the recording voltmeters of the suppliers of electric energy.

The nickel process for the purification of the finished gas from carbon disulphide by its conversion to hydrogen sulphide with subsequent removal by iron oxide is discussed in conjunction with other proposals for effecting this widely sought object. The nickel process, which it has taken something like ten years to bring to its present condition, has now become almost a complete replica of the experimental laboratory apparatus used by the late Prof. Vernon Harcourt. The general attitude towards gas lighting might have been a very different one had an earlier generation of gas engineers examined with a more intelligent sympathy the proposals of this chemist. A town's gas yielding on combustion only carbonic acid and water (such as to-day appears possible) would have occupied another *rôle* in the lighting of our houses than that furnished by the variable mixtures of gaseous combustibles with more or less deleterious diluents and sulphur-compounds endured by a long-suffering public with patience during the war.

The author uses the therm expression freely throughout his pages, and his calculations of efficiencies have thus an added value, especially those of the yields of the several systems of gasification. The importance of such a basis of comparison had been frequently overlooked until Sir Dugald Clerk drew forcible attention to it in discussing the relative values of the conversion of coal into electric and gaseous energy.

The author rightly classes naphthalene and cyanogen as impurities, not because they influence the products of combustion, but because of their harmful effect upon distributing systems. The work of Dr. J. S. G. Thomas upon the vapour tension of naphthalene finds its appropriate place in the chapter devoted to hydrocarbons, and the influence of this research upon the methods adopted for dealing with the difficulty is another instance of the value of scientific investigation in the laboratory as a guide to the large-scale practice of industry. Indeed, the most encouraging aspect of the volume under review is not only that a practical man has produced it, but that it has been produced for his practical *confrères*. Naturally consulting it for its wealth of technological information, they cannot fail to be impressed with the fact that each of the processes, in which as technicians they are interested, is shown to depend upon a foundation of science. Mr. Meade has thrown himself into his task with enthusiasm and has produced a compendium invaluable to those concerned in present-day gas supply, and one which is certain to affect considerably their future outlook. It is not his fault if it is to this class of reader that his work must mainly appeal, for, as has been said, he is a practical man writing for practical people. Yet there is room for another study upon altogether broader lines, which would lift up from the somewhat narrow circle of the literature of gas undertakings this remarkable example of industrial chemistry practised so long and so widely, yet so severely neglected by investigators and thinkers outside the pale of the gasworks. An unlimited supply of pure gas at low prices would revolutionise the aspect of, and the conditions pertaining to, life in all our towns. But the average member of the public judges town's gas by what it has done, not by what might be expected when some part of the time and thought bestowed upon its competing service is given to gas supply, now well on the road of its second century of usefulness.

Mathematical Recreations.

New Mathematical Pastimes. By Major P. A. MacMahon. Pp. x+116. (Cambridge: At the University Press, 1921.) 12s. net.

MAJOR MACMAHON, the author of the well-known "Combinatory Analysis," presents here, as a pastime, certain problems in tesselation and designing. Everything that he writes is carefully finished, and recreations invented by him are sure to be worth attention on their merits, while in this book the numerous scraps of poetry, with which, like Sylvester in former days, he adorns his pages, add a distinctive personal touch.

The work is divided into three parts. In the first and longest of them the object is to fill, subject to certain rules, a defined area by polygons all of the same shape and size, but each coloured or numbered, like dominoes, according to a different scheme. In the second part arrangements made according to the methods expounded in the first part are "transformed" so as to give a number of pieces of the same colour but of shapes which are all different; the result is the production of a jig-saw puzzle. In the third part we deal again with pieces all of the same size and shape, and the object is to design repeating patterns which can be used to cover an area.

The first part of the book involves the consideration of how to fill in a certain way a prescribed area with wood or cardboard polygons, which may be regarded as super-dominoes. The shape of an ordinary domino is a rectangle (the breadth of which is immaterial) with two ends or faces, on which numbers or pips can be inscribed, and, if we like, each number may be taken to indicate a particular colour: by using n numbers we can get $n(n+1)/2$ different linear dominoes. If our dominoes are triangular in shape, and from some central point within the triangle we draw lines to the angular points, we get dominoes with three faces, on each of which numbers or pips can be inscribed, and as before each number may be taken to indicate a particular colour: by using n colours we can get $n(n^2+2)/3$ different triangular dominoes. Similarly, by using n colours we can get $n(n+1)(n^2-n+2)/4$ different square dominoes, $n(n^4+4)/5$ different pentagonal dominoes, and so on. With each of these sets we can make up puzzles.

A particular instance will illustrate the kind of questions treated. Consider the case of equilateral triangular dominoes. If four colours are used we get a set of twenty-four different dominoes, and these can be put together (preferably fitting in a shallow box cut to the right size) to make a regular hexagon. Naturally the point in each domino from which the lines radiate to its vertices will be taken at its centre, thus dividing each triangle into three equal compartments, and facilitating the formation of symmetrical patterns. A consideration of what conditions can be imposed for arranging the dominoes next arises. For example, we may require the arrangement to be such that the colours of adjoining faces shall be alike, as also those of all the exterior faces; the solution, subject to this condition, is, among others, given.

The patterns formed are elegant, and the puzzle of fitting the dominoes together according to some imposed condition is sure to interest a good many people, some of whom are likely to become enthusiasts in the game. In the book the colours are indicated by numerals, and thus the results appeal to the mind rather than to the eye; this is a loss.

If the dominoes are right-angled triangles, we get a hexagon arrangement of a different shape. Further, we can play with sets selected from a particular full set and arranged in suitable geometrical figures. Similar problems arise from the use of square dominoes, hexagonal dominoes, etc.

In the second part, the author concerns himself with "transformations," necessarily unlimited in number, of arrangements like those above described. This is, in effect, an exposition of a method of making jig-saw puzzles of a certain type. Probably this has never before been reduced to a system, and it may be doubted whether those who cut out such puzzles will care to proceed by rule in the matter; but, if they do, here are hints and directions for their use.

In the third part, the previous investigations are applied to the formation of "repeating patterns," built up by arranging sets of pieces which fit together. Here the author enters on a field of decorative work in which there are already excellent technical books. He says that he has developed this subject much further, and that he has in hand a work entirely devoted to it. The subject is of importance to architects and pattern-makers, and is a recognised branch of arts and crafts.

The results of the problems set out in the first part of this book are singularly effective when colours are used, and provide numerous novel and interesting recreations of a certain type. We share the author's disappointment that the cost of printing nowadays has rendered it impossible to produce the book in colour. The questions considered in the second and third parts are of a more technical character, and are likely to appeal to the specialist rather than to the general reader: to the former they will open new and interesting lines of development.

The Fishing Industry and Scientific Research.

Ocean Research and the Great Fisheries. By G. C. L. Howell. Pp. 220+20 plates+3 charts. (Oxford: At the Clarendon Press, 1921.) 18s. net.

THE reconstruction spirit of the years 1918–9 was nowhere more evident than in its relation to the fishing industry. Even before the date of the armistice the owners of trawling and drifting vessels had met repeatedly and prepared a very noteworthy memorandum, which was presented to the President of the Board of Agriculture and Fisheries later on. At that time emphasis was very

naturally placed on the importance of a highly trained fishing population in regard to questions of national defence, and the immediate object of the memorandum was to interest the Government in this and other purely economic questions. In 1919, however, a series of committees met at Fishmongers' Hall under the presidency of Sir Edward Busk, and detailed recommendations dealing with administration, publicity, education, and scientific research were prepared, printed, and circulated. A beginning was made with the work of consolidating the statutes relating to fishery. Later on the British Trawlers Federation was formed, and proposals for the creation, by Royal Charter, of a British Fisheries Society were drafted. The author of the book under notice was mainly responsible for all this organisation. Throughout the whole movement scientific research was kept in the foreground, and its absolute necessity in any possible scheme of fishery reconstruction was recognised by everyone concerned. It was understood that the industry itself was prepared to back financially a sound programme of scientific and industrial research, and, without doubt, such programmes of education and research would now have been in practice but for the wholly unexpected partial collapse of the fishing industry that occurred in 1920.

These remarks will make clear what is the attitude taken up by Mr. Howell in writing his book. It is an account of the life-histories and economic significance of the various species of marine fishes, and it is very well done indeed. Apart from a few errors, inevitable, perhaps, in a work of this kind, it is a trustworthy account of the material of the marine fisheries, written in a plain but very attractive manner, fortified with clearly constructed statistical statements, very well illustrated and beautifully printed. But, much more than all that, it is a plea, on almost every page, for the further prosecution of marine research in relation to the fisheries, and it aims at the communication of the results of such work to the fisherman and owner of fishing vessels. It is a useful protest against the pedantry of the fisheries investigator. Little of what has been discovered has ever been presented in such a manner as to be understood by the industry in general—though this is quite practicable, as the book itself proves. Men of science almost always write for other men of science, though sooner or later their results must receive application, and this application would come all the more quickly if there were a true *liaison* between the administrators, the scientific workers, and the industry. The furtherance of such a working agreement is, all the way through, the main object of Mr. Howell's admirable book.

J. J.

Wegener's Displacement Theory.

Die Enstehung der Kontinente und Ozeane. Von Prof. Dr. Alfred Wegener. *Die Wissenschaft: Sammlung von Einzeldarstellungen aus den Gebieten der Naturwissenschaft und der Technik.* Herausgegeben von Prof. Dr. Eilhard Wiedemann. Band 66. Zweite gänzlich umgearbeitete Auflage. Pp. viii + 135. (Braunschweig: Friedr. Vieweg und Sohn, 1920.) 30 marks.

THIS book makes an immediate appeal to physicists, but is meeting with strong opposition from a good many geologists. This opposition is to be expected, for the author replaces the whole theory of sunken continents, land bridges, and great changes of earth temperature by a displacement theory.

Prof. Wegener's thesis is that the continents are of lighter material, and float like icebergs on a heavier plastic which reaches its highest level at the bottom of the oceans; the poles are not fixed relative to the plastic, and have occupied widely different positions, as, for instance, when Central Europe was a Sahara, or, again, when the great coal fields were laid down along a great circle (equator); land masses under gravitational influence move away from the poles and westwards.

Thus the Americas in their westward drift have heaped up the Andes and the Rockies. The South Atlantic opened early, but the northern portion did not exist until much more recent times. At the great Ice age, in fact, the glaciation in both hemispheres was due to an ordinary polar ice cap. India once stretched down over the Indian Ocean, being united to Africa and Australia. Since that time the Himalayas have been piled up, and Australia has left New Zealand far behind.

Actual measurements of continental and sea levels establish the fact that instead of there being a random distribution about one level there are two well-marked averages, a fact difficult to explain on any subsidence theory. Again, it was shown by Wilde that the earth's magnetic field can be closely imitated on a globe where iron sheets are placed over the ocean areas. On the present theory this is due to the plastic interior being richer in iron and rising higher under the oceans, where there is thus a thicker layer below the temperature at which iron loses its magnetic properties. Recent astronomical work has shown that the latitude of North American and European stations is increasing, but in the absence of measurements from the Far East we cannot prove that this is not due to a displacement of the pole.

The book brings forward a mass of geological

corroboration, although the author only claims to have "got it up" since the idea came to him. The revolution in thought, if the theory is substantiated, may be expected to resemble the change in astronomical ideas at the time of Copernicus. It is to be hoped that an English edition will soon appear.

The Earliest Forms of Society.

(1) *Primitive Society: The Beginnings of the Family and the Reckoning of Descent.* By Dr. E. S. Hartland. Pp. v+180. (London: Methuen and Co., Ltd., 1921.) 6*s.* net.

(2) *Primitive Society.* By Dr. R. H. Lowie. Pp. viii+453. (London: George Routledge and Sons, Ltd., 1921.) 21*s.* net.

IT is interesting to place these two books side by side in order to contrast the methods of attacking the problems involved in the study of primitive society which have been adopted by the respective schools to which the authors belong. (1) Dr. Hartland is one of the leading exponents of the view that there is a reasonable presumption that in the evolution of society wherever the patriarchal system now exists it has been preceded by the matriarchate. In the volume under notice he restates this view and summarises the evidence on which it is based in popular form. (2) Dr. Lowie, however, maintains that this theory is based upon an *a priori* assumption, and that Morgan and his followers, in their desire to formulate a logical scheme of social evolution, have distorted the facts by confining their attention to a single group of data. Pouring scorn on the heads of "the older school of anthropologists," he insists upon the empirical character of the evidence, and would have each case taken on its merits, subjected to intensive study, and treated as a whole.

After a review of the evidence on these lines, Dr. Lowie concludes that the theory of unilinear development is entirely fallacious and unwarranted. So far from the group organisation of the *sib* or clan being the foundation of primitive society, it is only one, and that frequently not the most important, of a number of forms of organisation to which the individual may belong. While he is prepared to allow that duplication of conditions may produce duplication of a sequence, as in the relation of polyandry and female infanticide, he formally abjures independent reproduction of the same series of "stages." He goes so far as to say that he is "not convinced of the reality of the totemic phenomenon," and for him the problem of totemism resolves itself into a "series of specific problems not related to one another." If, however, he believes in independent development only in the very limited degree indicated, neither is he a whole-hearted supporter of diffusion; while attaching full weight to diffusion, particularly in continuous areas, he recognises that it does not necessarily preclude independent invention within a limited scope.

It must be acknowledged that if Dr. Lowie's argument in favour of empiricism fails to carry conviction, he has done good service in emphasising the necessity for intensive study of all the facts of a given area as a whole. By concentration on the group organisation of the kin, the supporters of the evolutionary theory have sometimes been led astray. The existence of the family as a social unit at an early stage has been obscured by the view that the family emerged from the group. Dr. Hartland, indeed, speaks of "sexual promiscuity—relieved perhaps by temporary unions in the nature of monogamy." At the same time, owing to his preoccupation with kin organisation, he is unable "to bring Andamanese society within any category at present known." This fact does not, however, suggest to Dr. Hartland a modification of his conclusions, as might perhaps be expected; he prefers to await further evidence.

Our Bookshelf.

The Calendar: Its History, Structure, and Improvement. By Alexander Philip. Pp. xii+104. (Cambridge: At the University Press, 1921.) 7*s.* 6*d.* net.

THIS is not the kind of work that we expect from the Cambridge University Press. It contains numerous historical errors, and is not free from astronomical errors also. The author has endeavoured to guard against criticism of the latter by stating in his preface that his astronomical facts have been derived from the commonly available sources, and that he has disregarded "qualifying refinements known to modern astronomy but irrelevant to a calendrial purpose." This ambition has not prevented him, however, from stating the length of the tropical year to hundredths of a second, or the length of 4000 tropical years to an exact number of minutes. The introduction of these refinements, "irrelevant to a calendrial purpose," might have been pardoned, if they were accurate, which, unfortunately, they are not. But it is in the history of the calendar that the defects of the book are particularly displayed. The author ignores the two most valuable treatises on the subject, Ideler's "Handbuch der Mathematischen und Technischen Chronologie," and Ginzel's work which bears the same title. He writes in an easy way of Egyptian, Chaldean, and Chinese calendars;

but his knowledge of things "Chaldean" may be gauged by a footnote on p. 4, part of which is repeated in a footnote on p. 48. We quote the fuller note: "The 365-day year appeared at Babylon from Egypt after the overthrow of the Assyrian Empire by Nabonassar; but Chaldea subsequently developed a luni-solar, Egypt a solar, calendar." Comment is superfluous.

Bartholomew's General Map of Europe, showing Boundaries of States according to Treaties, 1921. Size 35 in. × 23 in. (Edinburgh: J. Bartholomew and Son, Ltd., 1921.) 1*s*. net.

THIS map of Europe, on a scale of 1 to 5,500,000, is designed to show the political boundaries and the chief lines of communication by land and sea. It makes no attempt to show the surface features of the land, and in that respect is open to criticism, although the adequate depiction of relief would certainly necessitate a reduction in the number of names. As regards boundaries, railway lines, and place-names, the map is full and accurate. We note, however, that the small States San Marino and Liechtenstein are shown by distinct colours, but are not named, while the principality of Monaco is named, but not indicated as an independent State. The map extends no farther north than about lat. 60° N., with the result that the new Finno-Russian boundary with the Finnish outlet to the Barents Sea cannot be shown. On the east its limits exclude the greater part of the Caucasus and the new States in that region. There is a small inset map showing the boundaries in 1914. The excellence of the colour printing and the legibility of the names make this a useful map for general reference purposes.

Oil Firing for Kitchen Ranges and Steam Boilers. By E. C. Bowden-Smith. Pp. ix + 102. (London: Constable and Co., Ltd., 1920.) 9*s*. net.

THE bulk of this book is taken up with descriptions of the Scarab burner and its application during the war to kitchen ranges in Egypt. The relative prices of coal and oil fuel in Egypt make it a big advantage to employ the latter, and the Scarab burner appears to have been of great service on account of its simplicity of construction. In the hands of quite unskilled persons kitchen ranges fitted with this burner have given very little trouble, and show a large saving in the cost of fuel. Thus the Turf Club at Cairo spent £E13·75 per week on coal and wood, and after conversion to oil fuel the weekly expenditure amounts to £E5·92. The drawing and descriptions of the burner and of the methods of fitting it to ranges will be readily followed even by non-technical readers. Some chapters are included on oil-firing steam boilers. It may be well to mention that a supply of compressed air is required; this presented no difficulty in Cairo, since there is a public service of compressed air in connection with the main drainage system, and air was taken from the mains.

The Chemistry of Colloids and Some Technical Applications. By Dr. W. W. Taylor. Second edition. Pp. viii + 332. (London: Edward Arnold and Co., 1921.) 10*s*. 6*d*. net.

THE second edition of this work, like the first, is well adapted to introduce the general student to the subject, the theoretical portions and the accounts of experimental procedure being well balanced. The amount of revision, however, appears, on examination, to be rather less than the author's remarks in the preface lead one to expect. Thus the "Valency Rule" still appears in its old and, as recent shattering criticism has shown, very spurious simplicity. Although earlier "complex" theories are given, Pauli's later and more thorough work is not mentioned. Recent results on protection and anomalous adsorption might also have found a place. With a subject in constant flux it is of course difficult to draw the line, but the author appears to have done so distinctly on the side of caution. In spite of these defects the book is still one of the most useful general text-books of colloid chemistry available in English.

The Fireman's Handbook and Guide to Fuel Economy. By C. F. Wade. Pp. viii + 84. (London: Longmans, Green, and Co., 1920.) 2*s*. 6*d*. net.

A GOOD deal of information which will be of service to firemen in helping them to understand what goes on in furnaces and boilers will be found in this little book. The author, however, is not quite happy in some of his fundamental explanations. Thus on p. 3 we read that "heat is a form of energy that can be measured as to quantity by means of a thermometer." Again, on p. 7 appear the following curious statements: "The only heat of the steam that does useful work is the amount added to the water to bring it just to boiling point." "It is much more economical to work at the highest possible pressure so that the latent heat may be low and the useful heat as high as possible." The sketches given in the book are clear, and will be understood readily by stokers.

A First German Course for Science Students. Second edition, revised. By Prof. H. G. Fiedler and Prof. F. E. Sandbach. Pp. x + 99. (London: Humphrey Milford: Oxford University Press, 1920.) 4*s*. 6*d*. net.

To many students of science an introductory course in German constructed to meet their special needs will be very welcome. The first portion of the work under notice consists of a number of passages descriptive of chemical and physical phenomena and experiments by means of which German technical phrases and words are introduced to the reader. Each passage is based on numbered paragraphs appearing in the outline of German grammar which constitutes the latter portion of the book. Here the examples given are, so far as possible, of a scientific nature. A useful vocabulary completes the book.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Test-plates for Microscopes and Microscopic Definition.

IN NATURE of September 1 last (vol. 108, p. 10) I suggested that dry films of some of the aniline colours might prove suitable surfaces on which to rule the very fine lines required for test-plates. Since that time I have made some trials with films, using various dyes and various materials for the ruling-point. The dyes were eosin, saffranin, cyanine, methyl-green, methyl-blue, and methyl-violet. The last of these gave the most uniform films, leaving, on the evaporation of the solvent, a bright surface free from structure. Cyanine gave good films, though not quite so opaque as the methyl-violet for the same thickness. The others, either from a tendency to crystallise or from drying with a dull surface, were not so satisfactory.

The points for ruling were of steel, garnet, carborundum, and diamond. In all cases, except that of steel, the natural points found among broken fragments were chosen, and I doubt whether, without a somewhat elaborate grinding tool, an artificial point could be made so sharp as that given by the natural breakage.

The points have to be selected by trial, as the microscope is of little assistance in determining their real terminal shape. The only apparatus which was at hand for ruling purposes was a Cambridge rocking microtome, and the minimum interval between the lines (which corresponds, of course, with the thinnest section it could cut) was somewhat greater than 1/60,000 of an inch. No great accuracy in the spacing of the lines could be expected, but it is to the credit of the design of this microtome that there was no difficulty in getting well-separated lines at 30,000 per inch, and occasionally the 60,000 lines were quite apparent.

The uncertainty with these close lines was due, I think, chiefly to the rather rough workmanship of the bearings of the rocking arms, but in part, perhaps, to those of the point-holder.

The only real difficulty in close ruling is that of finding a fine enough point and applying it to the surface with a small enough force.

As mentioned in my previous communication, this force must not exceed a small fraction of a grain, and should remove the film but not scratch the glass. In the trials the point-holder was made as shown in Fig. 1, the materials being reed and split-cane put together with silk splicing and shellac cement.

This light and rigid frame could rock on the needle-points, one of which entered a conical pit, and the other a **V**-shaped groove in a fixed fitting which replaced the knife of the microtome. The whole forms a pendulum the effective weight of which (a few grains) is, say, w, of length L, which if displaced by an amount a exerts a force wa/L in the direction opposite to the displacement. Thus by placing the plate to be ruled at a suitable distance from the undisturbed position of the ruling-point the force can be adjusted as required.

While the film is being advanced for a fresh line the ruling-point is withdrawn by means of a silk fibre leading from the swinging frame to a bell-crank mounted on the fixed support.

A few photographs of bands ruled with this apparatus are given in Fig. 2. All these were made with diamond points. With a newly ground hardened steel point the 30,000 band was well shown, but the tool soon became too blunt for any spacing less than 15,000 per in. Garnet and carborundum points lasted fairly well for 30,000 per inch lines, but, as might be expected, were inferior to diamond so far as wear was concerned.

In the earlier trials from ten to sixty lines were ruled for each band, but later it was found that four or five lines were quite sufficient to show all the effects which various kinds of stage illumination have on the definition.

It is only with opaque and very thin objects that

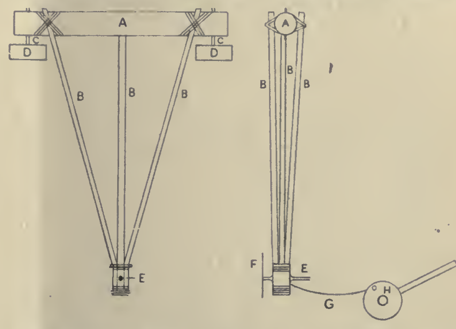

FIG. 1.—Holder for ruling point. A, Reed; BBB, split cane; CC, needle points; D, fixed support; E, diamond point; F, aniline film; G, silk fibre; H, bell-crank.

these can be examined to any advantage, thinness in this case being in comparison with the wave-length of light.

The methyl-violet films from which the photographs were taken were less than one-tenth of a wave-length in thickness, and, though not quite opaque, transmitted only a deep blue with some little red. The measurements of thickness were made by noting the displacements of the Newton's rings formed between a lens and the film at a place where part of the latter had been removed.

Test objects, such as diatoms, are much thicker than this, and, with them, what is seen in the field

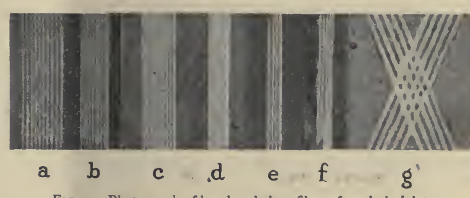

FIG. 2.—Photograph of bands ruled on films of methyl-violet.

a, 10 lines about 15,000 per in. ×350		*e*, 4 lines about 37,000 per in. ×600	
b, ,, ,, 20,000 ,, ,,		*f*, 5 ,, ,, 35,000 ,, ,,	
c, ,, ,, 17,500 ,, ,,		*g*, Intersection	
d, ,, ,, 25,000 ,, ,,		of bands 17,500 ,, ,,	

The photographic lines are not nearly so well defined as they appear when examined by the eye.

is merely a phenomenon in which the thickness and wave-length are both concerned.

I think that the late Lord Rayleigh was the first to emphasise the fact that optical definition in general depends on the difference of the optical length of the paths of the rays the convergence of which forms the images of contiguous objects. Let A_1, A_2 (Fig. 3) be two objects in a line making an angle β with the focal plane of the lens, B_1, B_2 their images, and f_1, f_2 the conjugate focal lengths.

The difference of length of the paths A_1, B_1, A_2, B_2 of rays making an angle i with the principal axis is $\alpha \sin (i+\beta)$, and unless the average of this for all values of i exceeds $\lambda/4$, the images B_1, B_2 will appear connected, and will not be clearly separated until the average is about $\lambda/2$. From this it may be seen that not only is it impossible to separate the images of objects in the focal plane which are much closer together than $\lambda/2$, but also that the same limit defines the distance out of focus at which objects may be placed without altering the character of their images. This is a point which is well brought out by the lines on the aniline films.

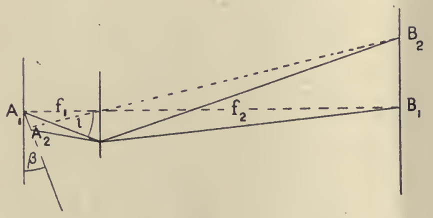

FIG. 3.

It may be asked what is the greatest magnifying power which can be usefully given to microscopes? Since objects closer together than $\lambda/2$ cannot form separate images, the greatest useful magnification is that which makes $\lambda/2$ visible to the eye.

A very good eye can just distinguish minutes of arc, or say objects separated by 1/350 in. at the distance of the eye from the stage. Then, taking the half-wave-length as the 1/100,000 of an inch, all details would be visible with a magnification of 100,000/350, or a little more than 280. Not all eyes, however, are capable of distinguishing minutes, and for convenience of observation, magnifications of twice this amount or more are used in practice, but the extra power reveals no new detail.

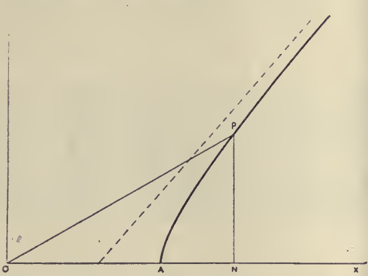

FIG. 4.—Form of plano-convex lens for the conversion of divergent rays into a parallel beam. O, Radiant point; OX, principal axis; PA, section of lens surface.

An idealised lens is merely a means of changing the radius of curvature of a wave-surface from f_1 to f_2 while preserving the constancy of the optical length of all the rays from focus to focus.

From these conditions the form of the lens which will achieve the result may be deduced. As a simple example, find the form of a plano-convex lens which will convert spherical waves originating at O (Fig. 4) into a parallel beam.

Let the convex surface of the lens cut the principal axis OX at A, and let the refractive index of the material be μ. The form of the surface is determined by the relation $OA+\mu AN=OP$. Elementary algebra shows that the curve PA is a hyperbola the asymptotes of which make an angle $\tan^{-1}\sqrt{\mu^2-1}$ with the axis of the lens. The complexity of actual objectives arises from the necessity of effecting the change of radius of curvature by means of spherical surfaces.

The Antitrades.

I AM glad to support the appeal for observations of the motion of cirrus-clouds in the inter-tropical region and elsewhere made by Prof. van Bemmelen in his letter on the Antitrades (NATURE, February 9, p. 172). It is very interesting that the results which he has obtained by direct observation, with only such additional information from dynamics as may be got from a consideration of the general character of the Australian pressure, should coincide so excellently with results which we obtained here from the calculation of the distribution of pressure at various levels, and the assumption that the wind flows along the isobars.

There are some details in Prof. van Bemmelen's maps which indicate a flow of air *across the equator* which I should be disposed to modify in view of the peculiar conditions under which such a transference of air must take place. I hope to give the details of the information that we have compiled about this subject at some future time, and confine myself for the present to saying that the atmosphere seems to be able to use the circulation of air round a strip of doldrum region as a means of providing for currents which flow westward on the south side, and eastward on the north side, of the equator in a general slope of pressure from south to north across the equator. Thus the doldrum region becomes a sort of elongated clockwise "centre" for the winds of the monsoon north and south of the equator.

I would add also to Prof. van Bemmelen's appeal for observations of cirrus a plea for the extension of observations with pilot balloons. Methods are now so well understood that the authorities could easily provide a *technique* which could be followed by those accustomed to surveying and others, and would provide invaluable information The committee of the British Association which concerns itself about the upper air has already taken up the question, and if anyone who is in a position to help in this matter would communicate with me or with the secretary of the committee, Capt. C. J. P. Cave, of Stoner Hill, Petersfield, we shall be greatly obliged.

NAPIER SHAW.

School of Meteorology, Royal College of Science, South Kensington, S.W.7, January 12.

The Isotopes of Mercury.

IT appeared to be so definitely one of the fundamental assumptions of physics that pure mercury has a constant density under given physical conditions that when Brönsted and Hevesy announced that they had separated it into fractions of different density (see NATURE, September 30, 1920, p. 144) it appeared desirable that the separation should be confirmed by other observers. One of us finds that when mercury (purified chemically and by distillation in a vacuum) is distilled in a very high vacuum the first sixth of the original mercury condensed is of lower density than the last sixth. The difference in density found for these fractions was 44 parts in 1,000,000. This

difference does not appear to be due to error in the density determinations for the mass found in different experiments, for a constant volume of the same specimen of mercury is constant to one part in a million, and with special care it is constant to a few parts in ten millions.

These experiments indicated, too, that any process of distillation would give some separation of the isotopes of mercury, and the question naturally arose: Upon what evidence has the density of mercury been regarded as constant? The matter had been investigated at the International Bureau of Weights and Measures by M. Marek in 1883, and he writes of the results which he obtained: "It is noticed in comparing these figures that the density of mercury varies slightly from one sample to another according to the method of purification. This result has already been obtained by Dr. H. Wild in a study of this subject specially undertaken." The results which Dr. Wild published in 1874 are not available to us. M. Marek, however, quotes results communicated to him by Dr. Wild, which, although ambiguously stated, make it appear as not improbable that Dr. Wild more than forty years ago separated mercury into specimens of different density.

Where did Terrestrial Life Begin?

The question raised by Dr. Macfie in his letter in Nature of January 26 concerning the place of origin of life on the earth is not one which directly concerns the meteorologist, but Prof. J. W. Gregory's comments upon it seem to call for discussion from the meteorological point of view. Dr. Macfie suggests that in the gradual cooling of the earth mountain-tops would first reach a temperature to make them habitable for human life, while the sea would for further centuries remain above the critical temperature. Prof. Gregory feels hesitation in accepting the conclusion reached that life would first be found on the mountains, considering that while "the mountain summits would have stood like islands above a sea of hot mist . . . any wind would have at times submerged the mountain summits beneath the lower atmosphere, and they would have been subject to violent fluctuations in temperature and moisture which would have been unfavourable to primitive life."

Now with an atmosphere of homogeneous composition it is impossible to warm a mountain summit by immersing it in warm air drawn from the lower layers; if the conditions are initially stable, adiabatic cooling sees to it that the warm bath of air becomes a cold one before the summit is reached. We must therefore assume that in these early days the earth's atmosphere was not homogeneous, but that hot layers of dense gas occupied the lower levels, while lighter constituents of low temperature floated above. In these circumstances a stirring up of the lower layers might raise the temperature at higher levels temporarily, but is there any evidence that such a condition existed? No trace of separation and stratification of the different gases under gravity is found in the troposphere at the present time, atmospheric turbulence being sufficient to maintain a similar constitution at all heights. If the gases were stratified in the manner suggested it would afford proof that vertical turbulence did not occur, and thus the very existence of stratification would show that the layers below never rose to the mountain-tops

Meteorological evidence does not seem to support Prof. Gregory's conclusion that the mountain-tops would be subject to such violent fluctuations of temperature as would render life impossible.

Dr. Macfie's letter (Nature, January 26, p. 107) accepts the common idea that the surface of the earth was formerly very hot—an assumption which is probably not well founded. If the earth was formed by accumulation of meteoric matter, it began its existence as a cold body the interior of which afterwards became heated by condensation, aided by atomic disintegration, while its surface was kept at a moderate temperature by radiation. It is difficult to believe that a globe so small, comparatively, as the earth could produce enough heat to raise its surface temperature anywhere near to the melting point; all igneous rocks are probably formed at some distance beneath the surface.

I imagine the first beginnings of life to have occurred at a very early epoch in the earth's evolution, namely, as soon as (1) the surface became warm enough and (2) elements capable of forming labile energy-storing compounds were present. It is not certain that solar radiation was necessary at first; the kinetic energy (heat and electricity) may have been derived from the earth itself.

Life at this stage would be of the humblest kind; we should scarcely recognise it as life nowadays. There would be no definite organisms, only diffuse substances trading in energy. Between this stage and the development of *cellular* organisms an immense period may have elapsed, and that period may have witnessed many intermediate stages. The achievement of the cell-form in living organisms must have marked a most important epoch in the history of life.

Chlorophyll may have been evolved at quite a late stage, as the culmination of a series of attempts at the formation of energy-fixing pigmentary bodies, most of which probably had iron as an essential ingredient.

The high stage of development shown in the earliest known fossils suggests that the geological period occupied by their evolution was vastly greater than the period since. The dawn of life may have occurred before there were either mountains or seas; all evidence of such early life has been obliterated by the metamorphosis and fusion of the deeper rocks.

Further discussion on this subject may be found in a paper by the present writer in the Proceedings of the Birmingham Natural History and Philosophical Society, vol. 11, pt. 1.

Rainfall and Drainage in 1921.

I have read with interest the letter of Mr. W. D. Christmas in Nature of January 26 concerning the rainfall and drainage at Rothamsted during the very dry year 1921.

A few years ago three rain-gauges were installed at Craibstone, the experimental farm of the North of Scotland College of Agriculture. Like the Rothamsted gauges, each of these is one-thousandth of an acre in area, and contains a block of soil which has been enclosed in its natural condition without disturbance. The soil at Craibstone differs greatly from the heavy loam of Rothamsted, and is composed of sharp granitic drift which is easily pervious to

water. Each of the gauges is 40 in. in depth. The rainfall alongside them is measured by an ordinary 5-in. Snowdon rain-gauge. The total rainfall recorded for the year 1921 was 17·86 in. In 1920 it was 32·25 in.; the average is probably about 30 in., but we have not yet obtained a record over a sufficiently long period to establish a trustworthy average. No. 1 drain-gauge is unmanured, and the figures quoted below refer to it. The drainage for the year from this gauge was 4·93 in. No drainage at all came through from early June to nearly the end of October, and during seven months, from the middle of May to the middle of December, the total drainage was 0·046 in., or less than one-twentieth of an inch. On the other hand, in 1920, when the rainfall was 32·25 in., the drainage was 18·09 in., and there were only two months, July and August, when there was no drainage.

In many parts of this district springs failed which were never known to have failed before, and there was great difficulty in many places in obtaining a sufficient water-supply. The reason for this is apparent when we find that from the middle of May until the end of the year practically no water passed through the subsoil.

Although the total rainfall for the year was so low, it was well distributed throughout the year and rain fell in every month. Quite a good crop was grown upon Craibstone Farm. The drain-gauges themselves as well as the surrounding field were under turnips, and both yielded a good crop.

The year 1922 so far as it has gone provides a great contrast to 1921. During the month of January more drainage came through No. 1 gauge than during the whole of the previous year. The rainfall recorded was 5·61 in., while the drainage from No. 1 gauge was 5·69 in. There were only two days during the whole month on which rain or snow was not recorded. The underground water-supplies are now being well replenished, and, although all the springs have not yet responded, there is no doubt that after the rainy month of January they should soon begin to recover.

Scientific Literature for Russia.

At the beginning of last year a British committee was formed with the object of sending books and other publications to men of letters and science remaining in Russia.

The committee was assured that any such works, if addressed to the House of Science or the House of Literature and Art in Petrograd, would reach their destination and would be much appreciated by literary and scientific men meeting there who were cut off from the intellectual life of the rest of the world.

An appeal was therefore made for funds to purchase works of a non-political type for dispatch to Petrograd, and Prof. Oldenburg, permanent secretary of the Academy of Sciences, furnished a list of books and other publications much needed by Russian *savants*. The books particularly desired were those which included accounts of current problems and developments of pure and applied science.

As the result of this appeal the sum of 448*l*. 17*s*. 5*d*. was subscribed, and several scientific societies, including the Royal Society, entrusted the committee with their publications for transmission to Petrograd. The Russian Trade Delegation undertook the dispatch of the books, and ten cases have been forwarded.

Prof. Oldenburg, writing on December 21 last, expressed the deepest gratitude of scientific workers in Petrograd for this stimulating intellectual aid, and says that they have been placed in a special reading-room at the House of Savants, where they are consulted by a large number of students throughout the day, and have been the means of reviving scientific interests and work. He sends the most cordial thanks of men of science in the city to all who have contributed towards the stimulus to scientific investigation which the new publications have given them.

Having thus established contact with scientific men in Russia and enlightened them as to the progress of research from which they have been separated by political circumstances beyond their control, the committee is of the opinion that its task has been accomplished. Of the fund remaining in its hands the sum of 50*l*. has been expended upon books desired by the University of Latvia, and a small balance will be handed over to the Universities Committee of the Imperial War Relief Fund.

The committee gratefully acknowledges the generosity of the response to its appeal, and believes that the intellectual relief thus afforded will do much to strengthen Russian scientific life.

A statement of accounts, audited by Messrs. W. A. Browne and Co., chartered accountants, will be sent to anyone who desires a copy.

Cyclic Conditions and Rejuvenation in Hydroids.

Several colonies of *Tubularia indivisa* which have lived in the aquaria for three years are noticed as exhibiting alternating periods of activity and rest. Broadly speaking, the hydranths die off about midsummer and reappear about midwinter, the times in one particular case for the growth of new lengths of hydrocaulus and for the formation of new hydranths being December, 1919, January, 1921, and January, 1922, and in another January, 1920, January, 1921, and December, 1921, the hydranths in each case finally dying off in the intervening periods between the end of May and July. Colonies obtained from moderate depths in January generally show clearly marked new ends to their hydrocauli, such new growth often being an inch or more in length.

At the same season died down colonies of Stauridium and Melicertidium in the aquaria, and Clava, Syncoryne, Campanularia, Antennularia, Plumularia, Halecium, etc., in the sea are found showing signs of rejuvenation.

In a paper on "The Effect of Hydrogen-ion Concentration and Oxygen Content of the Water on Regeneration and Metabolism in Tadpoles" (*Journ. Exper. Zool.*, 1920), M. E. Jewell shows that rate and amount of regeneration increase with increase of oxygen content of the water, but decrease with decrease in temperature, and that the optimal P_H for regeneration is at or near neutrality. In connection with these experimental results it is interesting to note that the above regenerations begin when the sea temperature is approaching its minimum, at which time the oxygen content is greatest, and continue with increasing rapidity during spring, when increasing alkalinity further stimulates growth and an ever-increasing food supply is available.

In view of our incomplete knowledge of the interrelations of physical factors in the sea it is extremely

hazardous to make binding statements, but it seems probable that increase of light stimulating photosynthesis will tend to set back the incidence of maximum oxygen content, especially in a partly closed area like the Clyde Sea area, so that it does not actually coincide with minimum temperature, in which case it would appear that light and high oxygen content are the primary factors influencing these rejuvenations. RICHARD ELMHIRST.

Marine Biological Station, Millport.

Tin Plague and Arctic Relics.

IN view of the apparent public interest in my letter in NATURE of January 19, possibly a further note on the subject may be permitted. One letter I have received was from a Government Department concerned with food supplies for the Navy, and I was asked a number of questions. The first one (to my surprise) was "The name of the firm who produced the article referred to." That had never occurred to me! However, in an endeavour—which proved successful—to reply to that query, I found a note which seems worthy of reproduction here.

In an "Appendix to the Narrative of a Second Voyage in Search of a North-West Passage and of a Residence in the Arctic Regions during the Years 1829, 1830, 1831, 1832, 1833, by Sir John Ross," pp. cxi–cxiv, is "an analysis of fluids, etc.," from which the following extract is made, in addition to which is a report on brine, wine, rum, lemon-juice, and mustard, from Fury Beach :—

"I am indebted for the following article to my friend, Mr. Thomas Rymer Jones, who, in conjunction with Mr. Hemmings, submitted the articles I gave them to a careful examination, and made the following report, which requires no comment, as the acquirements of these gentlemen are known to qualify them highly for such an investigation :—The provisions, of which the following account is given, had been lying exposed to the climate for eight years, in the latitude of seventy-three degrees and forty-seven minutes north, and longitude of ninety-one degrees and forty-seven minutes west, and very little above high-water mark. The preserved meats, with few exceptions, were the manufacture of Messrs. Gamble and Co., and being enclosed in tin cases, could not be discovered by animals who depend on the sense of smelling; these were cylinders of various sizes, the ends of each becoming concave or convex, according to the degrees of contraction or expansion caused by the climate, secured them against bursting from its effects, and the contents were found to be in nearly the original state: these consisted of beef, roasted and boiled; veal, mutton, spiced meat of various kinds, turnips, parsnips, and carrots, all of which were found to be in excellent preservation. The soups, which were preserved in quantities from a quart to a gallon, were excellent, and we left a considerable quantity behind, but no meat of any kind. The flour, which was preserved in iron-bound casks, and had been likewise exposed for eight years to the climate, was found to be in good condition; for although in many cases the hoops had slackened, so as to admit moisture into the cask, it penetrated but a short way, while the whole of the interior was perfectly sound. The bread, of which there were many casks, was in a good or bad state, according to the soundness of the cask which contained it, and we employed ourselves in separating the bad from the good and put all into repaired casks. A part of this, and also of the flour, is sufficient with the addition of the remaining soup to sustain the life of twelve men for a year. Owing to the pickles being also in cask they had suffered much, the vinegar having leaked out of most of them: fifty of these, and twenty-five of lemon-juice, are also left, at a little distance south of the house, and covered with coals, as the most effectual way of preserving both."

T. SHEPPARD.

The Museums, Hull.

A New Series of Spectrum Lines.

WITH a long hydrogen tube, viewed end on, as a source, lines have been observed at $4{\cdot}0^5\mu$ and $2{\cdot}6^3\mu$, which, according to Bohr's theory, may be explained as due to an electron falling from the fifth to the fourth and from the sixth to the fourth rings respectively, forming the first two members of a new series.

Lines have been observed at wave-lengths $1{\cdot}8^8\mu$, $1{\cdot}2^8\mu$, $1{\cdot}0^9\mu$, $1{\cdot}0^1\mu$, and $0{\cdot}9^5\mu$. These form the first five members of the Paschen series due to an electron falling into the third ring from the fourth, fifth, sixth, seventh, and eighth rings respectively. The first two of these were observed and accurately measured by Paschen.

The first line of the new series is approximately one-fourth the intensity of H_α; the first Paschen line, more intense than H_α in the ratio 4 : 3.

Araucaria imbricata.

REFERRING to the note in NATURE of January 19, p. 87, about this archaic tree ripening seed, may I say that it will do so regularly in this country if it gets a chance? But whereas it is diœcious, seed is produced only where male and female trees are planted near enough to each other for the wind to carry the pollen from the male catkins to the female cones. In 1906 I took Dr. Augustine Henry over to Castle Kennedy. There had been a heavy gale a few days before, and the ground about the fine avenue of Araucaria was thickly strewn with ripe seed, whereof we collected a bagful. Some we ate, treated like chestnuts, and found them excellent. Others I caused to be sown, and have now a hilltop planted with more than twelve hundred monkey-puzzles, some of which are 12 ft. high. The female tree produces seed only in alternate years as the cones take two seasons to ripen. HERBERT MAXWELL.

Monreith, Whauphill, Wigtownshire, N.B.

Some Problems of Long-distance Radio-telegraphy.

IN the portion of the abridgment of my Trueman Wood lecture on the above subject published in NATURE of February 2, p. 140, I quoted an instance taken from a paper by Dr. Van der Pol of the ratio between the observed receiving aerial current and that calculated by the diffraction formula for the case of the Nauen–Darien transmission. It appears, however, that a numerical error was made in Dr. Van der Pol's original calculation, which, however, he corrected in the *Phil. Mag.* for July, 1920. This correction, unfortunately, I overlooked. It appears that the correctly calculated value of the received current is not $0{\cdot}6 \times 10^{-13}$ amp., but $1{\cdot}9 \times 10^{-10}$. Hence the actual current is only seven thousand times that predicted by the diffraction formula, and not two million times. This discrepancy does not, however, invalidate the conclusion that wave-diffraction alone cannot account for long-distance wireless telegraphy. J. A. FLEMING.

London, February 14.

Flowering Dates of Trees along Main British Railway Routes.

By J. Edmund Clark.

A FEW months ago the Editor of NATURE sent me, as joint editor of the Phenological Reports published by the Royal Meteorological Society, an interesting problem. He said:—"It has been pointed out on several occasions that in travelling from the West of England (Devon and Cornwall) to London, fruit trees are usually seen to be much more forward as regards flowering nearer London than in the West." I was therefore asked whether I had, among the "phenological observations, records of such flowering dates arranged according to longitude so as to determine whether fruit trees do, normally, bloom earlier near London than far away, and whether this is true also in passing from London to the East."

Our thirty years' records give no basis for a direct reply, since of set purpose garden flowers and fruits were excluded by the late Edward Mawley from the thirteen selected blossomings. These begin with the hazel (mean for the British Isles, February 13) and close with the ivy (October 2). The many varieties of most of our fruit trees is the obvious ground for their exclusion.

It seemed, however, worth attacking the problem indirectly, even though at first the supposed earliness appeared to be improbable. The four fruit-time plants in our list, blackthorn, garlick hedge-mustard, horse chestnut, and hawthorn, average two and a half days earlier in England, S.W., than in England, S.E. and E., in our thirty years' means.

The basis for investigation required:—

(1) Sufficient stations. For the first time in the thirty years 1920 supplies these, thirty-five being available.[1]

(2) The blackthorn gives us the opening, the other two trees the closing, stages of fruit flowering.

(3) Unfortunately 1920 was abnormally early, and therefore prolonged. This is shown by the following table, giving the days early compared with the mean:—

1920		S.W.	S.E.	E.
Blackthorn, early	days	30	24	20
Chestnut and may, early ..	,,	10½	18	12
Prolongation, fruit flowering ..	,,	19½	6	8

The possible results on relative conditions may well be serious, especially as to insolation. Obviously any such effect would be most marked in England, S.W.

(4) The isophenes (lines of equal flowering date) have for the first time been tested for agreement with Prof. Hopkins's Bioclimatic Law, recently formulated and found to hold well in the United States. Starting from a given station, this postulates a retardation of four days in flowering for every additional 400 ft. of altitude, 1° of latitude and 5° eastward in longitude[2]; the reverse for negative values. Both he and we have found it fairly trustworthy for the British Isles, and he for Western Europe. This has enabled me to reduce the records to sea-level, so as to see whether there is any factor other than the higher elevations along most of the way until London is approached.

(5) Since it is most difficult faithfully to record the *average* date of first flowering, after taking the mean of the three trees for each of the thirty-five stations available (those within twelve to fifteen miles of the selected railway routes), the mean of two or more adjacent stations was taken, so far as possible. In this way we have fifteen sets of records available.

(6) Unfortunately the L.S.W.R. route from Exeter to London was useless, no records being available between Exeter and Fleet.

The results are shown in the following table:—

Mean Flowering Date, Sloe, Chestnut, May, 1920.

	Stations	Date
I.	Penzance, Camborne, Falmouth ..	April 8
II.	Polperro (2), Duloe	,, 6
III.	Launceston, Hexworthy, Tavistock ..	,, 6
IV.	Tiverton, Wellington, Taunton	March 30
V.	Winscombe, Portishead	April 2
VI.	Falfield, Bath	,, 1
VII.	Winsley, Marlborough	,, 6
VIII.	Oxford (2)	,, 3
IX.	Fleet, Farnham, Hampton Wick ..	March 29
X.	A. Harrow, Watford	April 9
	B. Purley (Surrey) (2)	,, 3
XI.	A. New Barnet, Woodford	,, 2
	B. Hayes and Bromley (Kent)	March 28
XII.	A. Maldon, Hatfield Peverel, Lexden ..	April 5
	B. Maidstone	,, 2

I. to IX. closely follow the G.W.R. from Penzance to London; X.A, XI.A, and XII.A continue on north of the Thames Estuary to Colchester; X.B, XI.B, and XII.B south of it to Maidstone.

Of I. to IX. the earliest date is just before reaching London; the latest in the foot of Cornwall. East Devon and Somerset fall little behind London; whilst East Cornwall, West Devon, and North Wilts are nearly as late as I. Hopkins's latitude and longitude corrections, however, intensify the contrast, the date relative to London working out to April 18.

Eastwards from London flowering dates north of the Thames are retarded, but to the south scarcely at all, Hayes and Bromley (Kent)—March 28—having the earliest date of all.

Before considering possible explanations, two cautions must be reiterated. The transfer here of Hopkins's Law values is still only tentative, and the dates of observation may well be subject to a margin of error of a day or two. Making full allowance for these, we may still believe that general observation is verified, the more so that,

[1] See our Phenological Report to the Royal Meteorological Society for 1920 (Part 3), 1921.

[2] As a fact, the law is more general, governing all seasonal plant phenomena; the regressive phases, of course require the reverse of the above statement.

as noted already, the earliness of 1920 was most strongly marked in England, S.W. We therefore conclude that London is at least a week earlier than Penzance in its fruit flowering; also that, at any rate in an early season, while further advance eastward south of the Thames estuary results in little change, there is a decided retardation on the opposite bank as one proceeds in a north-easterly direction. It is difficult to account for the Harrow-Watford delay. Further on the cooling influence of the North Sea and of east winds may come into play. The isophenes cut the East Coast, the direction varying N.E. to N. East-wind exposure may partly account for the retardation at Purley (Surrey) and on the Wiltshire downs. It is not easy offhand to suggest the reason affecting the extreme south-west, which must be largely influenced by ocean conditions. One would expect the fruit-flowering season to share in the relative earliness shown by the means of all twelve flowers (omitting ivy), ranging from February 6 to July 15. One may, however, note that, for the first six months, isotherms and isohels taken together slightly favour the London area, but in April the reverse was the case.

The East Devon and Somerset earliness was fully expected. Each year the isotherms show a remarkable uprush of warmth along the Severn sea and watershed and a corresponding lie of the isophenes. In 1920 the isotherm bulge reached the borders of Yorkshire.

Having thus considered the query raised, an extension of the subject may be of interest along two other lines through London, which I have worked out for the sake of comparison. These are: (1) The L.B.S.C.R. from the Isle of Wight and on by the East Coast route to Edinburgh and Ross-shire; (2) from East Sussex and on by the West Coast route to the Glasgow district. Round London much the same stations come in along all three lines. The comparison is best made by placing the two series side by side, arranged roughly by latitude (50¾° to 57¾°). The numbers in brackets show the number of stations in each group.

As one expects, both series give a decided delay with latitude and longitude. Hopkins's corrections for these from London to Ardross Castle (+6¼° and +4°) give the relative date for the latter April 18. For Glasgow (4½° and 4°) we get April 26, the value round the Firth of Forth (4½°, 3°) being April 12.

Either Hopkins's Law needs modification for the period in question, more than is indicated by the whole period, or there are special influences at work, such as oceanic effects, prevalence of east winds, and propinquity of hill and mountain masses. Nor need these be mutually exclusive.

To investigate them more complete data are required. For instance, we hope shortly to have mean values for a considerable number of stations over the thirty years of our records. The most obvious effect at present is perhaps the retardation for the spring period in question, due to high elevation, and even more the propinquity of hill and mountain masses. Is this due to the lag effect of their winter cooling? Snow would still be lying on the Welsh mountains in blackthorn days.

May I, in conclusion, direct the attention of readers of Nature to the need for yet further observers, especially in the districts indicated by the lacunæ in the tables and the fact that the L.S.W.R. from Exeter could not be used? Either my colleague, Mr. H. B. Adames (33 Holcombe Road, Ilford), or myself (Asgarth, Purley) will gladly give further information, or observing forms can be had direct from the Assistant Secretary of the Royal Meteorological Society, Cromwell Road, S.W.7. When we see the prominent position elsewhere, especially in the United States, taken by phenological work in its bearing on horticulture and agriculture, we realise the need in this country for greater unification in and concentration on its investigations.

Since the above was in print Prof. Hopkins has sent us the typed copy of an unpublished exhaustive discussion of the bioclimatic association

Mean Flowering Date, Sloe, Chestnut, May, 1920.

between North America and Eurasia. He has correlated the two continents by using for the four years 1916–1919 the flowering date of hawthorn, *Crataegus oxyacantha*, at our station of Tenbury, Worcestershire, with the date for the leafing of the hickory, *Carya alba*, at his own station of Kanawha Farm, West Virginia, adopted as base for intercontinental correlations. Working from the latter, he found the closest agreement with our 25-year mean; less divergent, he considers, than errors of observation.

In order to test his calculation, and again starting from his U.S.A. base, Prof. Hopkins worked out the theoretical means for the eleven British meteorological districts. Scotland N. and Ireland S. differed by 11 days, Scotland W. by 5. These three districts are our worst, from paucity of observers. But this year we have completed (see Q.J. Roy. Met. Soc. for October last) the 30-year mean values, worked out entirely afresh and carefully weighted for defective records. Compared with these far more trustworthy figures, the discrepancies found by Prof. Hopkins are reduced to three, one, and four days respectively, the eight other districts also giving closer agreements. Thus, though as yet unknown to Prof. Hopkins, his results are well confirmed.

The success obtained seems to imply that from absolutely trustworthy phenological records of seasonal changes for a single station in the northern hemisphere for one single plant, the whole seasonal phenology for any other plant or crop can be postulated for any other spot in North America, Europe or Asia. The publication of this paper should be an important step in this branch of applied science.

Obituary.

Dr. James Francis Bottomley.

By the death of Dr. Frank Bottomley—due to pneumonia following influenza—which occurred on January 16 at the early age of forty-seven, the country has lost the services of a chemist, physicist, technician, negotiator, and manager of men of quite exceptional ability and integrity.

Heredity and environment conspired to make Dr. Bottomley a man of science. His great-grandfather was Dr. James Thomson, professor of mathematics in Glasgow University; his great-uncles were Lord Kelvin and James Thomson, F.R.S., professor of engineering in Queen's College, Belfast, and Glasgow University; while his father was the present Dr. James Thomson Bottomley, F.R.S., of Glasgow University. His mother died when he was three years old, but five years later his father married the widowed sister of Lord Kelvin, and between the boy and his stepmother there arose an attachment which deeply influenced his character.

From eight to thirteen years of age Dr. Bottomley was educated at Bloxham, near Banbury, where he became interested in science, but his school career was cut short by influenza in the epidemic of 1888. After a long period of convalescence he entered the University of Glasgow—first as a non-matriculated, and afterwards as a matriculated, student—under Prof. Ferguson, Lord Kelvin, and Prof. Jack. In his second year he was laid up with scarlet fever and so lost the chance of taking his degree. In 1894, at nineteen years of age, he went to Germany, and, after about six months with a German family, entered the University of Heidelberg. Here he came under the influence of Victor Meyer and Prof. Gattermann, and also studied physics under Prof. Quincke, mathematics under Prof. Konigsberg, and mineralogy under Prof. Rosenbusch. In 1897 he obtained the Ph.D. degree "multa cum laude," and returned to Glasgow, where he entered the university chemical laboratory and physical laboratory.

In 1898 Dr. Bottomley was awarded a research studentship for three years, the first of which he spent at Glasgow, the second at Owens College, Manchester—where he was elected research student and afterwards research fellow under Prof. W. H. Perkin—and the third at University College, London, under Sir William Ramsay. Here, according to Ramsay, he showed "manipulative skill of the highest order," and proved himself "an accomplished chemist and a courteous gentleman." In 1901 he joined the standardising laboratory of Kelvin and James White, and a year later was associated with the Newcastle-upon-Tyne Electric Supply Co., and became also chemical expert to the firm of Merz and McLellan (then C. H. Merz), consulting electrical engineers.

In 1902 Dr. Bottomley began his great work on silica fusion on a commercial scale by means of the electric furnace. The research was carried out at Wallsend, and by skilful and systematic experiment he eventually solved the many technical difficulties which had defeated prior experimenters, and, as managing director of the Thermal Syndicate, Ltd., became responsible for the commercial, as well as for the scientific and technical, development of the work. In 1910 his company received the gold medal for its exhibit of fused silica ware (vitreosil) at the Brussels Exhibition, and the gold medal for a similar exhibit at Turin in 1911.

In 1914 the process, which was by this time well established, afforded almost the only material then manufactured in the United Kingdom in which acids could be concentrated for the manufacture of explosives. The output of the works was increased tenfold, and the burden of designing and supervising the necessary extensions and of the technical management fell, for the most part, on Dr. Bottomley. So successful was he as a manager that throughout the war and up to the time of his death the works were entirely free from labour troubles. After the armistice he was mainly occupied in

developing methods of manufacture of vitreosil globes for incandescent gas lighting, which he brought to a successful conclusion only shortly before his death.

Quiet and diffident in manner, slight in build, and far from robust, Dr. Bottomley gave little outward sign of the strength that was in him both of character and ability, and as he published but little and never advertised himself at all, he was not well known except to his associates. By these he was recognised as a man of exceptional judgment, business ability, and integrity, and, besides "being" the Thermal Syndicate, he was a director of Kelvin, Bottomley, and Baird, of Chas. Tennant and Co., and of the Blagdon Manure and Alkali Co. He was also (until the war) a director of the Deutsche-English Quartz Schmeltz G.m.b.h., which carried on the quartz fusion processes in Germany.

Dr. Bottomley was married in 1913 to Miss Dorothy Couves, and leaves a widow and two children. He was an outstanding example of the advantage of giving administrative and business responsibility to a man of character and scientific training. R. A. S. Paget.

Prof. Max Verworn.

By the death of Prof. Max Verworn at Bonn on November 23 last, a notable figure, who could ill be spared on account of the breadth of his outlook, has been lost to biology. Verworn had just completed his fifty-eighth year, having been born in Berlin on November 4, 1863. He received his school and early university education in his native city, and graduated Ph.D. in Berlin in 1887, and later M.D. in Jena in 1889. After graduation in medicine, his interests being then largely zoological, he paid a long visit to Villefranche and Naples, and later continued his investigations along the coast of the Red Sea. On his return to Jena Verworn was appointed assistant in the Physiology Institute, and in 1891 was duly approved as *Privatdozent*. After a few years' work, including a second visit to the Red Sea, he became extraordinary professor of physiology in Jena in 1895. In 1901 he was called to Göttingen as professor of physiology, and in 1910, on the death of Pflüger, he became the professor of physiology at Bonn. Verworn received many academic distinctions. In this country he was an Sc.D. of Cambridge and an LL.D. of St. Andrews. He was also an honorary or corresponding member of many of the Continental scientific societies, in Moscow, Vienna, Rome, Halle, etc. Twice he was invited to visit America, on the second occasion as Silliman lecturer in the University of Yale.

Verworn owed his special, almost unique, position in physiology to the catholicity of his interests. He had been impressed from his earliest student days with the value of zoology, and much of his best and most original work was done in the physiology of the invertebrates of all classes, although perhaps those of the marine fauna engaged his warmest attention. He used this material with skill and ingenuity in his interpretation of physiological problems in general. Undoubtedly the work by which Verworn is best known is his "Allgemeine Physiologie," which was translated into English by Prof. Lee. This book, which is a mine of information in the lesser-known aspects of general physiology, appeared in 1894, and was immediately recognised as a work of outstanding merit. It has gone through many editions. His Silliman lectures on irritability brought together his special views on the nature and function of the nervous system, a subject which had interested him from the first; indeed, one of his earliest contributions (in 1889) to attract attention bore the title "Psychophysiologisch Protistenstudien." He also held very definite views on the functioning of living tissue in general, and his name will always be associated with his interesting biogen hypothesis.

That Verworn's interests were not confined to the study, in any strict sense of the word, of ordinary physiology and zoology is evidenced by his writings on the psychology of primitive art and on the evolution of the human spirit. Certainly for many years before the war he was very interested in archæological and ethnological problems, and the writer has a most vivid memory of a conversation with Verworn, in which he gave an extraordinarily enthusiastic account of a visit to several of the Indian tribes resident in the south-west of the United States. He had visited these tribes to study the nature of their art, more particularly their colour combinations. Verworn also had a profound knowledge of the history of early art in Europe, and a very genuine interest in numismatics.

In spite of his many interests, Verworn managed to edit, with success, two physiological journals, one the *Zeitschrift für Allgemeine Physiologie*, founded by himself, and later, after his appointment to Bonn, the famous Pflüger's *Archiv*. E. P. C.

Col. Willoughby Verner.

Col. William Willoughby Cole Verner, who died on January 25 at his home at Algeciras, was in many ways a remarkable man. He was a product of the Army at its best and a living denial of the too-often-quoted saying that Army officers think little and have no interests beyond sport and their "shop." Col. Verner will be remembered not only as the writer of the history of the Rifle Brigade and as the inventor of the luminous magnetic and prismatic compass and of other aids for military sketching and surveying, but also as an authority on the wild birds of South Spain and the discoverer of many of the rock shelters in South-West Spain that had been painted and decorated by Neolithic or Eneolithic man. Articles on the latter were published by him in the *Saturday Review*, and these brought him into relationship with the Abbé H. Breuil. The result was a careful survey of the whole district with regard to prehistoric man. Col. Verner, while bird-hunting near Ronda, had once noticed paintings on the walls of a cave near the top of the "sierra." This led to the publication by Breuil, Obermaier, and Verner of the first of an interesting group of Palæolithic cave paintings, which recall the northern group of France and Cantabria. But the memory of Col. Verner

will always live in the hearts of those who were privileged to be with him for a time at his little shooting cottage near the Laguna de la Janda. His kindness, knowledge, and interest in everything were especially noticeable, but at the same time his soldierlike love of order was never absent. Woe betide the guest who returned the salt-jar to the place where the pepper-pot should have been! The Army has lost a competent officer who continued to work for it in many ways after being physically incapacitated during the South African War from active service; science has lost an earnest follower; but, above all, some of us have lost a real friend.

M. C. BURKITT.

Current Topics and Events.

SIR FRANCIS GALTON was born on February 16, 1822, in the same year as Mendel. The Eugenics Education Society is celebrating the anniversary in a dignified way with addresses on Galton's contributions, not only to eugenics, the cause that was nearest his heart, but to statistics and geography as well. Galton was in more than one striking way the complement of his cousin, Charles Darwin, but especially in this respect: that his imagination was fired with the idea of man's evolution going on. Darwin thought more perhaps of the descent of man, Galton of the ascent; but it is very interesting that the *doyen* among eugenists should be Darwin's own son. The Eugenics Education Society has been fortunate in having had Major Leonard Darwin for many years at its helm. Of course, Charles Darwin and Francis Galton were entirely at one, though the angle from which they regarded man was a little different. What Galton grasped so firmly was the idea of *man evolving*, and that no longer mysteriously, but under the influence of factors which are discoverable by, and amenable to, scientific methods. He had the vision of the control of life, of applying our knowledge of the factors in evolution to the guidance and acceleration of that evolution. This was to him, as he said, "a virile creed, full of hopefulness, and appealing to many of the noblest feelings of our nature." In celebrating the anniversary there is reason for congratulation and encouragement, for Galton's doctrines have made rapid headway. It must be confessed, however, that the need for more enthusiasm is great. Thus we see from Prof. Karl Pearson's letter to the *Times* of January 18 that although the Galton Laboratory is nobly housed, its undertakings—especially in the way of publication—are sadly hampered by lack of funds. The same hindrance affects the Eugenics Education Society, and it is plainly a matter for regret that new knowledge of high importance should be lying unpublished and that educational efforts to diffuse the "virile creed" should have to be slackened when they are so urgently needed.

ON February 19 occurs the tercentenary of the death of Sir Henry Savile, to whom Oxford owes the foundation of the Savilian professorships of geometry and astronomy. Accounted by his contemporaries—among whom were Casaubon and Scaliger—"a man of admirable skill in the Greek and Latin languages and a laborious searcher and generous publisher of the remains of venerable antiquity," Savile was one of the first scholars of the age. Born near Bradley, Yorkshire, in 1549, he matriculated at Brasenose College, became a fellow of Merton College, was elected a proctor of the University, and at one time taught Greek to Queen Elizabeth. From 1585 he was Warden of Merton, and from 1596 Provost of Eton, holding both positions until his death, which took place at Eton. The chairs of geometry and astronomy were founded by him in 1619, Briggs being appointed to the former and Bainbridge to the latter. Among the distinguished men who have held one or the other have been Halley, Sir Christopher Wren, Bradley, Baden-Powell, Pritchard, H. J. S. Smith, and Sylvester. Before Briggs took over the duties of the chair of geometry Savile himself delivered thirteen lectures upon the first eight propositions of Euclid's "Elements," and these were published in 1620. Though Savile's contemporary, Sir Henry Billingsley, sheriff and Lord Mayor of London, had published the first English translation of Euclid's "Elements" in 1570, and the chair of geometry at Gresham College had been founded in 1596, the preamble to the deed of foundation of the Savilian professorships stated that "geometry is almost totally unknown and abandoned in England."

A BILL was introduced in Parliament on February 8 providing that summer time should begin on the last Saturday in March (or, if that is Easter Eve, on the preceding Saturday) and end on the first Sunday in October. These dates have been fixed in agreement with France and Belgium, as a difference in the dates causes confusion in through services. Many astronomers suffer some inconvenience from the use of summer time, but probably most of them would make little of this if they were persuaded that the majority of the community recognised it as a boon. All must agree that, if used, it is well to have its beginning and end fixed in a regular manner. On theoretical grounds, of course, the principle of summer time does not differ from that accepted long ago, when Greenwich time was introduced for the whole of Great Britain. This involved the use of a standard meridian, differing for some places 7° from the local one, and the increase from 7° to 22° is a matter of convention; the first has no more basis in theory than the second. On scientific grounds the main objection to summer time is the confusion due to the varying standard, and the measure now proposed should do something to remove the difficulties thus caused.

ON January 24 Mr. T. East Lones, of the Patent Office, read a paper before the Newcomen Society on "Mechanics and Engineering from the Time of Aristotle to that of Archimedes." Aristotle contains little of interest to engineers, but it was the extraordinary

belief in his views that led to the trouble after Galileo, by his experiments from the Leaning Tower of Pisa, had shown the falseness of Aristotle's dictum that the velocity of a body falling in a given medium was proportional to its weight. The works of Archimedes are of a much more valuable nature. His solution of problems regarding floating bodies, his determination of the centre of gravity of various surfaces, his invention of the Archimedean screw, and his investigation of the lever place him among the greatest pioneers in the acquisition of knowledge. Though it is generally believed that Archimedes asserted that he could move the earth with a lever had he a place to stand upon, it appears that Archimedes contemplated the use of compound pulleys for this purpose, and not the lever. After referring to the engines of war of those days, Mr. Lones gave interesting details of the two great aqueducts which led water into Rome, the old Roman roads, and other civil engineering works. He also referred to the tools used by the ancients in the execution of their works.

In an article in the *Quarterly Review* for January Mr. E. Howell discusses at length the problems connected with river control in Mesopotamia. The Tigris and Euphrates are exceptional rivers in the way that their lower reaches break down, throwing off effluents, although eventually they unite and enter the Persian Gulf through a single mouth. Between Bagdad and Ezra's Tomb, a distance of some four hundred miles, the Tigris receives only two tributaries, but throws off five huge effluents besides innumerable smaller channels. The Euphrates in the same portion of its length shows even more marked degeneration, breaking into a thousand petty waterways in the tract known as Shamiyah, reuniting near Shamawah, and again spreading into a waste of shallow waters in Lake Hammar. There seems to be much evidence that this state of affairs is the outcome, not of natural causes, but of man's interference with the river acting through long ages and accentuated by the difference in both rivers between the levels of low water and high flood. It is suggested that if this interference is scientifically regulated the rivers will revert to former conditions, in which their value to man will be greatly enhanced in respect of definite channels and deeper beds. Unregulated riparian cultivation for ages has resulted in the formation of many effluents and the blocking of the river-bed by silt dug from the channel at low water in the construction of the irrigation canal from the shrunken river to the squatter's date-grove. Mr. Howell, quoting Major Walton, explains the process in full, and contends that the remedy lies in the control of riparian cultivation, the regulation of the course and nature of irrigation channels, and the construction of dams or locks on the chief effluents. Some work of this nature carried out from 1916 to 1919 has had noticeably beneficial results on the navigability of the Tigris.

From the report on the administration of the Meteorological Department of the Government of India in 1920–21 it appears that the suspension of wireless telegraphy from ships at sea during the war has rendered it more difficult to give information as to the development and path of storms. The system was started again in May, 1920, although it will necessarily take time to regain the former efficiency. The absence of such wireless information apparently led to wrong deductions relative to the movement of a storm in the Arabian Sea between June 6 and 13. There was, fortunately, little loss of life, but in Junagadh State the storm did a large amount of damage; 16,000 houses are said to have fallen, 22,000 trees were uprooted, and 7700 cattle died. Upper-air observations are being made in connection with military flying on the part of the Royal Air Force and for the use of civil aviators when the route Bombay–Calcutta–Rangoon is opened. The number of special forecasts and warning messages sent from Simla during the year was 2994, and from Calcutta 929. In connection with cases of heatstroke among British soldiers, information was supplied to local medical authorities when the wet-bulb temperature rose above 75° F. Registration of rainfall has been carried out during the year at 2915 stations, for which the returns are published. The growth in departmental activity and changes in total cost are shown by diagram for the last thirteen years. Mention is made of the loss to the Indian Service of Dr. G. C. Simpson through his appointment as Director to the Meteorological Office of the Air Ministry.

The Royal Astronomical Society was founded as the London Astronomical Society in February, 1820, but did not gain the prefix "Royal" until 1830. At the annual general meeting of February, 1920, the president, Prof. A. Fowler, gave an address on the origin and early days of the society, which had Sir W. Herschel for its first president. There was some opposition to its formation on the part of the Royal Society, but this did not last long. The centenary of the society will be celebrated next June; it will open with a conversazione on the evening of June 8. On June 9 there will be an historical meeting in the morning and a scientific one in the afternoon; at the former three addresses will be given, one introductory by the president, an historical address by Dr. Dreyer, and a biographical address by Prof. Turner. The society will dine together in the evening. A volume dealing with the history of the society is in course of preparation, and may be issued during the year. It is divided into ten decades, and is the work of several collaborators, but Dr. Dreyer, who is well known as an astronomical historian, has contributed the largest share. It will be illustrated by portraits of some of the more celebrated presidents of the society.

The *Times* of February 13 makes the following announcement:—A Committee has been appointed to discuss the co-ordination of the work of the various Admiralty chemical laboratories. It will consider the scope of all work now carried out at the various laboratories in the Admiralty service, and will report

whether any changes can be made with due regard to the requirements of each department interested in the work to avoid dissipation of energy, overlapping of duties, and unnecessarily different conditions of service. Mr. W. J. Evans, Director of Establishments, is chairman, and Mr. J. Lang, of the Admiralty C.E. Branch, is secretary; the other members being Eng. Vice-Adm. Sir George Goodwin, Engineer-in-Chief; Capt. R. R. C. Backhouse, Director of Naval Ordnance; Comdr. L. E. H. Llewellyn, Chief Inspector of Naval Ordnance; Mr. F. E. Smith, Director of Scientific Research; Mr. W. J. Berry, Director of Warship Production; and Mr. F. Ward, Deputy-Director of Armament Supply.

THE Fuel Research Board of the Department of Scientific and Industrial Research has appointed a Committee to advise upon the sampling and analysis of coal. The *personnel* of the Committee is as follows:—Prof. T. Gray (chairman), Prof. J. W. Cobb, Mr. J. T. Dunn, Dr. J. S. Flett, Mr. G. Nevill Huntly, Mr. S. Roy Illingworth, Mr. J. G. King, Dr. C. H. Lander, Dr. R. Lessing, Mr. C. A. Seyler, Mr. F. S. Sinnatt, and Prof. R. V. Wheeler. Secretary, Miss N. Renouf. It is intended that the methods recommended by the Committee shall be adopted in connection with the physical and chemical survey of the national coal resources. Communications for the Committee should be addressed to the secretary at 16 and 18 Old Queen Street, Westminster, London, S.W.1.

WE are glad to see that the Portsmouth Literary and Philosophical Society, which was established in 1869 but was afterwards discontinued, has been revived. There must be many citizens of all classes in such a place as Portsmouth, with the adjacent residential district of Southsea, who will find interest and stimulus in the activities of the new society. The programme for the current session includes descriptive lectures, field excursions, and sectional meetings of students and workers in various departments of knowledge, such as literature, history, geography and geology, botany and zoology, psychology, and social science. The president, Sir Richard Gregory, will deliver his presidential address on "The Influence of Science" to-morrow, February 17. Mr. E. Heron-Allen, F.R.S., and Sir John Brickwood are vice-presidents of the society, Lt.-Col. J. H. Cooke chairman of council, and Mr. C. W. Ball, Whittington Chambers, King's Road, Southsea, honorary secretary.

CONTINUING its discussion of the State and provincial museums, the *Museums Journal* in its February issue suggests that this country is not merely falling behind others, but has even taken a step backward. "The post created for dealing with provincial museum work at the Board of Education has now been vacant for more than a year." The regulations formerly "laid before Parliament annually, as part of a Board of Education command paper, setting forth the conditions upon which loans of objects and grants of money were made to provincial museums, were last issued in 1910." These alleged facts seem curiously inconsistent with the activity of discussion on the educational use of museums that prevailed a few years ago at the Ministries of Reconstruction and Education. This is not altogether to be explained by the necessity for economy, since what is wanted is not so much fresh expenditure as the co-ordination and utilisation of the means ready to hand.

DONATIONS to the Maidstone Museum during the past year include an albino specimen of the American grey squirrel, shot near Maidstone; a lower jaw of the woolly rhinoceros found in Maidstone, and remains of the cave lion and the mammoth from the river-drift at Aylesford; a miscellaneous collection containing many fine minerals, formerly the property of Prof. Arthur Connell, F.R.S., of St. Andrews; fragments of a baked earth bowl associated with a calcined flint nodule (? a pot-boiler) found at Borough Green; three pieces of Late Celtic pottery from the Cherry Orchard Estate, near Maidstone; and a copy of William Smith's "Delineation of the Strata of England and Wales, etc.," published in 1815. The large number of other donations bears witness to the confidence placed in the curator, Mr. J. H. Allchin.

As from April 1 next, the importation into the United Kingdom of the plumage of birds not expressly excepted under the Importation of Plumage (Prohibition) Act, 1921, will be prohibited. The Board of Trade may, however, under section 2 (4) of the Act, "grant to any person a licence subject to such conditions and regulations as they may think fit authorising the importation of plumage for any natural history or other museum, or for the purpose of scientific research or for any other special purpose." All applications for licences under this sub-section should be addressed to the Imports and Exports Licensing Section, Board of Trade, Great George Street, Westminster, S.W.1.

THE annual meeting and excursions of the Somersetshire Archæological and Natural History Society will be held at Clevedon on July 4–6. The president-elect is Sir William Boyd Dawkins.

MR. G. V. COLCHESTER has been appointed to the post of geologist on the Geological Survey of the Anglo-Egyptian Sudan in succession to Mr. C. T. Madigan, who now holds a lectureship in geology at Adelaide University.

AT a meeting of the Institution of Automobile Engineers on February 8 Mr. E. L. Bass read his paper on "Engine Lubrication," for which the Daimler premium for the session 1920–21 was awarded. Lt.-Col. D. J. Smith was elected president for the session 1922–23.

ON Tuesday next, February 21, Sir Arthur Keith will begin a course of five lectures at the Royal Institution on "Anthropological Problems of the British Empire," Series 1: Racial Problems in Asia and Australasia. The Friday evening discourse on February 24 will be delivered by Prof. J. Joly on "The Age of the Earth."

THE thirty-first annual meeting of the Royal Society for the Protection of Birds will be held at the Middlesex Guildhall, Westminster, S.W.1, on Tuesday,

February 21. The chair will be taken at 3 p.m. by the Duchess of Portland, and an address on the work of the society will be delivered by Viscount Grey of Fallodon.

AT the annual general meeting of the Royal Meteorological Society on January 18 the following officers were elected:—*President:* Dr. C. Chree. *Vice-Presidents:* Mr. C. L. Brook, Mr. W. W. Bryant, Mr. R. H. Hooker, and Dr. E. M. Wedderburn. *Treasurer:* Mr. W. Vaux Graham. *Secretaries:* Mr. J. S. Dines, Mr. L. F. Richardson, and Mr. Gilbert Thomson. *Foreign Secretary:* Mr. R. G. K. Lempfert. *Council:* Dr. J. Brownlee, Mr. D. Brunt, Mr. C. J. P. Cave, Mr. J. E. Clark, Mr. R. Corless, Mr. Francis Druce, Mr. J. Fairgrieve, Col. H. G. Lyons, Mr. Henry Mellish, Sir Napier Shaw, Dr. G. C. Simpson, and Mr. F. J. W. Whipple. Communications should be addressed to the secretaries at 49 Cromwell Road, South Kensington, S.W.7.

THE following officers and members of council of the Royal Astronomical Society were elected at the anniversary meeting on February 10:—*President:* Prof. A. S. Eddington. *Vice-Presidents:* Dr. J. L. E. Dreyer, Sir F. W. Dyson, Prof. A. Fowler, and Prof. H. F. Newall. *Treasurer:* Col. E. H. Grove-Hills. *Secretaries:* Dr. A. C. D. Crommelin and the Rev. T. E. R. Phillips. *Foreign Secretary:* Prof. H. H. Turner. *Council:* Prof. A. E. Conrady, Dr. J. W. L. Glaisher, Mr. P. H. Hepburn, Mr. J. Jackson, Dr. H. Jeffreys, Prof. F. A. Lindemann, Dr. W. H. Maw, Prof. T. R. Merton, Prof. J. W. Nicholson, Mr. J. H. Reynolds, Lt.-Col. F. J. M. Stratton, and Mr. H. Thomson.

THE annual general meeting of the Physical Society of London was held on February 10, and the following officers and members of council were elected:—*President:* Dr. A. Russell. *Vice-Presidents:* Lord Rayleigh, Prof. T. Mather, Mr. T. Smith, and Prof. G. W. O. Howe. *Secretaries:* Mr. F. E. Smith, "Redcot," St. James's Avenue, Hampton Hill, and Dr. D. Owen, 62 Wellington Road, Enfield. *Foreign Secretary:* Sir Arthur Schuster. *Treasurer:* Mr. W. R. Cooper. *Librarian:* Dr. A. O. Rankine. *Other Members of Council:* Mr. C. R. Darling, Prof. C. L. Fortescue, Dr. E. Griffiths, Dr. E. H. Rayner, Mr. J. H. Brinkworth, Mr. J. Guild, Dr. F. L. Hopwood, Dr. E. A. Owen, Dr. J. H. Vincent, and Dr. G. B. Bryan.

A TRANSLATION of the Nobel Prize address delivered by Prof. Max Planck before the Royal Swedish Academy of Sciences on "The Origin and Development of the Quantum Theory" will be published at an early date by the Oxford University Press.

READERS in search of book bargains should see Catalogue No. 454 of Messrs. William Glaisher, Ltd., 265 High Holborn, W.C.1, and Catalogue No. 424 of Mr. F. Edwards, 83 High Street, Marylebone, W.1, in which are to be found the titles of many science books offered at greatly reduced prices. The works in the first-named list are publishers' remainders; those in Mr. Edwards's are second-hand.

Our Astronomical Column.

FIREBALL OBSERVED IN SUNSHINE.—Mr. W. F. Denning writes that on February 7, at 3.55 p.m., he observed a brilliant fireball descending in the northern sky. The sun was shining at the time, and the firmament was almost cloudless. The fireball moved with moderate speed, varying in size and lustre as it fell, and its motion was directed to the north-north-west point of the horizon, but it disappeared when 21° in altitude. Its brilliancy was such that had it appeared at night the heavens would have been strikingly illuminated. The fireball was observed from other places, and it appears certain that it was moving from a radiant point near the star Capella. There is a well-known shower of brilliant meteors from this region in the month of February. It is hoped that further observations of the recent fireball will come to hand so that its height, velocity, and exact direction may be computed.

A PRINTING CHRONOGRAPH.—The printing chronograph was invented by Prof. G. W. Hough, of Dearborn Observatory, in 1885. It is briefly described by Prof. Sampson in the Monthly Notices, R.A.S., for April, 1903. Its use leads to a decided increase of accuracy in the recording of transits or other time observations as compared with older forms of chronograph. This becomes of particular importance now that the use of the recording micrometer has considerably reduced the errors in the signals sent from the telescope to the chronograph.

The Société Genevoise, 95 Queen Victoria Street, E.C.4, is now showing a new printing chronograph. There are three discs, marking minutes, seconds, and hundredths, which revolve in an hour, a minute, and a second respectively; the first has to be set by hand to agree with the clock; the adjustment of the others is effected automatically. When a signal is sent the discs are pressed momentarily against a typewriting ribbon, behind which is a paper tape; the tape is moved automatically after each signal; there is thus no waste of paper between the signals, and a night's record is comprised in moderate limits; this counterbalances the greater awkwardness of a tape record as compared with a cylindrical one for a long night's work. The discs are electrically driven by a motor the E.M.F. of which is 12 volts, supplied by secondary cells. The net weight of the installation is 66 lb., and gross weight 110 lb.

NOVA PUPPIS 1902.—The *Gazette Astronomique* for December last records the discovery of a new star by Miss Woods from the negatives taken at the Harvard Observatory. The position of the nova was R.A. 8h. 9m. 36·4s., decl. −26° 15·8′ (1900); the star was thus situated on the fringe of the Milky Way, the region in which novæ are usually found. The following is a summary of the facts recorded:—1901 (invisible), <16 mag.; 1902, September 24, <10·3 mag.; November 19, 7 mag.; December 6, 7 mag.; 1903, June 3, 10·5 mag.; and 1905, <14·5 mag. (invisible afterwards). More than 400 negatives of the region were examined. Judging from the facts recorded, it looks as if the nova reached its maximum some time before November 19, 1902, because it is not usual for new stars to maintain their maximum magnitude for such a long period as seventeen days. No photographs of the spectrum were taken.

Research Items.

Birthdays in Relation to Intelligence.—In the Proceedings of the Royal Society of Edinburgh (vol. 41, No. 17) Mr. M'Callum Fairgrieve discusses the annual incidence of intelligence. He experimented with 368 boys, using chiefly the American Army tests, supplemented by some of the tests used by Dr. Cyril Burt. His object was to see whether the time of year of birth bore any relation to intelligence. The results seem to show that boys born in the late spring months are in danger of developing less intelligence than those born about October. It is pointed out that naturally there are exceptions, some of the clever boys having birthdays in the less intelligent period, but that on the whole, and his ages range from ten years to eighteen years, the generalisation is correct. The author suggests that it would be valuable if the test were repeated in other districts. Certainly it is a problem worth studying systematically.

Apogamous Reproduction.—In a short account of experiments in apogamous reproduction with some species of Hieracium, Dr. C. H. Ostenfeld (*Journal of Genetics*, vol. 11, No. 2) describes the occurrence of several apogamic mutants which remain true in apogamous reproduction. It is believed that the numerous microspecies in the subgenus Archieracium have been produced in this way, being the after-effects of earlier crossing. The cytological studies of Rosenberg with species of this group have shown that there are irregularities in the chromosome distribution during the reduction divisions. The occurrence of apogamic mutants is plausibly accounted for on the assumption that some such irregularity may occur in the development of the egg-cell, thus producing an aberrant individual which will breed true later by apogamous reproduction.

Sex-reversal.—In a very interesting paper on sex-reversal in frogs and toads Mr. F. A. E. Crew (*Journal of Genetics*, vol. 11, No. 2) discusses all the recorded cases of females exhibiting all intergrades towards the male condition. In extreme cases the transformed animal appears as a typical male, but may retain the Müllerian ducts or a few ova amid the spermatic tissues. Such an animal behaves and functions as a male, but that it retains the germinal constitution, *i.e.* the chromosome complex, of a female has been shown by crossing such a transformed female with a normal female. The young (774) were all females, showing that the chromosome complex of these "somatic" males had remained unchanged. The transformation acts through the internal secretions of the gonads, and the process of sex-reversal is very similar to that which causes the production of freemartins in cattle, as described by Lillie. The general opinion that Bidder's organ in the frog is a rudimentary ovary is questioned on the basis of these experiments.

Cotton in the French Sudan.—The shortage of raw cotton for the mills of France, due largely to the decreasing export from the United States, has directed attention to the possibility of large-scale cotton production in the French Sudan. With this end in view the Comité du Niger has been formed. Some details of the schemes which this committee proposes, together with a large-scale map, are given in *La Géographie* for December last. Briefly, the idea is to irrigate certain areas along both banks of the Niger in the vicinity of Segu, which it is proposed to connect by rail with both Grand Bassam and Dakar. On the left bank the Nyamina irrigation canal would leave the Niger near Bamako, the railhead of the line from Dakar. A barrage would be erected at Sotuba and another at Sansanding, some twenty-five miles below Segu, from which the Sansanding Canal would run eastward for about 140 miles. Land on the right bank is to be irrigated by the Segu Canal and its branches, which leaves the river at the Sotuba barrage. These schemes, if carried out in full, would give some 10,000 square miles of irrigated alluvial ground. Farther east along the Niger towards Timbuctu vast areas of useful land could also be reclaimed for cotton-growing.

Potash in Marl and Greensand.—The value of glauconitic marl and greensand as sources of potash is once more raised in the Annual Report for 1920 of the Department of Conservation and Development, New Jersey. At Elmwood Station, where green marl is 49 ft. thick, an acre of land covers approximately 9400 tons of potash. The average potash-content of the marl over a wide area is as high as 6·60 per cent.; but commercial development, unfortunately, awaits new methods of extraction.

Antarctic Geology.—Mr. J. M. Wordie's report (Trans. Roy. Soc. Edin., vol. 53, pt. 2, 1921, 4s.) on "Geological Observations in the Weddell Sea Area," in connection with the Shackleton Antarctic Expedition of 1914–17, is specially notable on account of its photographic illustrations. The view of South Georgia in Plate 1 provides an exceptionally fine picture of a land escaping from glacial control, with its high cirques in the background, frost-sculpturing on the arêtes, a valley glacier still pushing out to sea, and the bared bed of another, preserving the very form of the terminal fan, though the ice itself has shrunk back towards the hills.

Rainfall in Mysore.—Rainfall registration in Mysore for 1920 is the subject of a report by Mr. N. Venkatesa Iyengar, Meteorological Reporter to the Mysore Government. During the year rain was observed at 226 stations. The greatest rainfall recorded in one day was 11·88 in. at Agumbi, in the Shimoga district, on July 24; in the previous year the heaviest fall was 15·40 in. at Nagar on June 20. The mean rainfall for the year in the State was 28·96 in., whilst the average is 36·07 in.; in 1919 the mean for the State was 38·97 in. There was a deficiency of rainfall in 1920 in every district, ranging from 6 per cent. in the Shimoga district to 49 per cent. in Tumkur. Data are given showing the monthly rainfall for the several districts and the mean percentage departure from the average. Similar information is given for the seasonal rainfall, the four seasons into which the year is divided being cold-weather period, January and February; hot-weather period, March, April, and May; south-west-monsoon period, June, July, August, and September; and the retreating south-west-monsoon period, October, November, and December. In the hot-weather period, the south-west-monsoon period, and the north-east-monsoon period there was a general shortage of rain. Rainfall is collated for the several river-basins for 1920 and compared with the average fall for twenty-seven years, 1893–1919. The monthly average fall is given for each station. The average rainfall for the year ranges from 316·59 in. at Agumbi, in the Shimoga district, to 15·61 in. at Nayakanhatti, in the Chitaldrug district. The geographical distribution of rain in 1920 and the average are well shown in two maps at the end of the report.

Burst Tubes in the Claude Process.—In the synthesis of ammonia under pressures of 1000 atmospheres and at reaction temperatures of 500°–550° C., as in the Claude process, many working difficulties might have been anticipated One of these is described by M. Georges Claude in the *Comptes rendus* of the Paris Academy of Sciences for January 16. In the reaction between the hydrogen and nitrogen large amounts of heat are produced, and these were removed by the circulation of molten lead round the vertical reaction tubes. This system has led to accidents through bursting tubes, and it has been found that the crack starting the break in the tube always commences on the outside, and the effect is shown to be due to the difference of temperature between the inside and the outside of the thick-walled tube. This difference, about 200° C., causes the warmer internal layers to exert an enormous pressure on the cooler outer layers, and this is in addition to the normal pressure of working. The tubes are now packed in kieselguhr to prevent this dangerous temperature-gradient, and other means will have to be adopted to remove the heat set free in the combination of the two gases.

Industrial Motion Study.—Most of our knowledge of "time and motion" study comes from America, and is chiefly dependent on the investigations of F. W. Taylor and F. B. Gilbreth. The object in view was the standardisation of human industry. Taylor picked out his best workmen and determined the shortest times taken by them to perform the various stages of the industrial operation under investigation. The times were added together, and, after the addition of a certain allowance for unavoidable delays, they formed the standard time or task. This required the workman to do three or four times as much work per day as he had done previously without much regard being paid to his state of fatigue. Gilbreth gave more attention to the methods of work, and endeavoured to ascertain what were the quickest movements possible in the various steps of an industrial operation. These he regarded as the best. In Report No. 14 of the Industrial Fatigue Research Board Mr. Eric Farmer gives a full summary of previous work on time and motion study, and subjects it to severe criticism. As the result of his own observations in industries such as that of sweets production, he concludes that the most important principle of motion study is rhythm rather than speed. The best set of movements is not the quickest set, but the easiest set. The quickest set may cause too much strain on the workers and produce undue fatigue. It is better to make the movements of the hands required in an industrial operation in curves, without sudden changes of direction, rather than in straight lines. Increased production was not specially aimed at, though, as a matter of fact, it invariably occurred when a proper system of movements was introduced. In the instances quoted it went up from 38 to 50 per cent.

Alcohol as a Motor Fuel.—A brief survey of the work of the Fuel Research Board in regard to power alcohol since the publication of the Board's interim memorandum in 1920 is given in the second memorandum on "Fuel for Motor Transport," which has recently been issued. This publication contains the results of inquiries which have been made as to the possibility of producing commercial quantities of alcohol within the Empire at a price which would render its use practicable as a motor fuel. The facts that nearly all the vegetable substances proposed as raw materials for the manufacture of spirit are already in great demand as foodstuffs or for industrial purposes, and the usually high cost of production, provide the key to the main results of the inquiries. So far as the British Isles are concerned, there is little prospect of adding materially to the supplies of power alcohol from home-grown raw materials. The utilisation of molasses, however, in overseas countries where this by-product is not yet fully employed for other purposes, and the cultivation in the tropics of cêrtain roots and tubers with a high starch content, offer prospects of a limited production of alcohol which may be equal to no more than local demands. Synthetic production on a commercial scale in the British Isles is unlikely, but in Canada and Australia, especially in the latter country, the process is not impossible with the development of available sources of cheap electricity. The best chance of the production of power alcohol on a large scale for export appears to lie in the perfection of a chemical or bacteriological process for the production of alcohol from the inexhaustible supplies of vegetation in tropical and sub-tropical regions. The researches to this end initiated by the Board have not yet resulted in a practical commercial process, but some progress has been made, especially on the bacteriological side.

Endurance Limits of Metals.—During the recent war the question of the strength of aeroplane parts and other problems of materials under repeated stress brought the whole subject of "fatigue" phenomena of metals to the attention of the National Research Council, U.S.A. The result was the organisation of an investigation by the co-operation of this body with the Engineering Experiment Station of the University of Illinois. We have received Bulletin No. 124 from the University entitled "An Investigation of the Fatigue of Metals," which is a progress report of the first part of this investigation, having for its object the determination whether or not there exists any clearly defined relation between static properties and the ability to resist repeated stresses. The work has been carried out by H. F. Moore and J. B. Kommers. Two types of rotating-beam testing machines were used, one reversed bending testing machine, and one reversed-torsion testing machine. The materials tested consisted of both carbon and alloy steels, the range of composition in the former case being considerable The authors conclude that for metals tested under reversed stress there is a well-defined critical stress at which the relation between unit stress and the number of reversals necessary to cause failure changes markedly. Below this critical stress the metals withstood 100,000,000 reversals, and, so far as can be predicted from test results, they would have withstood an indefinite number of such reversals. The name "endurance limit" has been given to this critical stress. No simple relation was found between this and the elastic limit. Rather curiously, the Brinell hardness test appears to furnish the best index of this figure, the reason for which is by no means clear. The authors find that the endurance limit for ferrous alloys can be predicted with very fair accuracy by the measurement of the rise of temperature under reversed stress applied for a few minutes. This is the development of a test proposed by Mr. C. E. Stromeyer. In none of the alloys tested did the endurance limit under completely reversed stress fall below 36 per cent. of the ultimate tensile strength; for only one alloy did it fall below 40 per cent., while for several alloys it was more than 50 per cent. The tests reported indicate the effectiveness of proper heat treatment in raising the endurance limit of ferrous alloys.

The Air Conference.

IT is yet too early to judge of the effects on the future of aeronautics of the official and unofficial speeches made in the course of the Air Conference at the Guildhall, London, on February 7 and 8, but there can be no doubt as to the seriousness of the various speakers or the representative character of the gathering. The dominant note of the Air Minister's address was lack of belief in the future of civil aviation in Europe, an expression of opinion not shared by the members of the conference. It was asserted by more than one speaker that a subsidy is needed by the London–Paris air service only because France has given a large measure of assistance to her designers, constructors, and pilots. Whilst the British aircraft companies have carried six passengers per machine on each journey, the corresponding figure for French aeroplanes is two; on the other hand, the major portion of the goods traffic has been taken in the aircraft of other countries.

The conference was opened by the Secretary of State for Air, Major F. E. Guest, but for the greater part of its proceedings Lord Weir was in the chair. Matters relating to the Air Force were not under review, as at the previous conference—a development towards secrecy in the new fighting Service which may be noted. Provision was made for the reading of papers on the first day, the morning being devoted to civil transport and the afternoon to technics and research for both aeroplanes and airships. The second day was fully occupied by discussion from the assembled experts from the various branches of aeronautics. The depression produced by Major Guest was not removed by the carefully prepared paper read by Lord Gorell, the Under-Secretary of State for Air, and speaker after speaker was moved to protest. Lord Gorell's paper showed that air activity is great in many parts of the world, and that other countries are spending more money on development than is Britain. Probably Lord Weir voiced the general sentiments when he indicated a better quality for the endeavours of this country, and suggested that enough had been learnt to justify the development of the Imperial air route, England–Egypt–India. A permanent committee is now being formed to deal with the matter, and the only resolution put to the conference endorsed the view and was acceptable to the Air Ministry.

Col. Bristow, with an intimate knowledge of the working of the London–Paris air service, remarked that "it is lamentable in the extreme that in this year, the fourth after the Great War, the British commercial air fleet should consist, all told, of fewer than twenty aeroplanes; in fact, on the day the paper was written there were only six or seven."

The exhibits on the aerodrome at Croydon on the day preceding the conference must then have constituted the whole of the existing commercial air fleet, and the number may be contrasted with an output of 1000 aeroplanes per week at the close of the war. The smallness of the civil, as compared with the military, side was referred to by Sir Samuel Instone, of the Instone Air Line, on the following day, when he mentioned the fact that the subsidy for civil aviation is 200,000*l*., whilst the expenditure on the Air Force has been 18,500,000*l*.; of the 200,000*l*. it is proposed that the spending of half on new craft should rest with the Air Ministry, and not with the transport companies.

The discussion on this section of the subject (civil transport) turned on the importance of civil aviation to progress. There was a strongly expressed view that the new system of transport has come to stay, and the president of the Federation of British Industries attended the conference to give the blessing of the business community and to announce adherence to the theory of a sound subsidy in the early stages of development. That the industry will ultimately support itself on a commercial footing was not doubted, but no one accepted as satisfactory the statement of the Air Minister that in certain directions Britain could wait for ten years and then start again.

Where is the principal stumbling-block? The Director-General of Civil Aviation indicated it as "the military be-all and end-all of aviation." The present complete stoppage of airship work and the unsympathetic attitude of the Air Ministry add further arguments in the same sense. Major Scott's paper on airships finished with an expression of opinion that commercial airships were immediately possible as technical devices, and support was given to this view in the discussion. Another instance of Air Force dominance is furnished by the experiments on a helicopter, mentioned by Lord Gorell and Gen. Bagnall Wild; it appears to be regarded by certain Air Force officers as important and a subject for immediate experiment and research; technical experts and men of science regard expenditure of money on the helicopter as waste owing to the lack of promise of success for very many years to come. The Brennan helicopter at Farnborough is being built in secrecy, and, so far as can be gathered, the Aeronautical Research Committee has not been consulted.

This lack of balance between military wishes and technical possibilities gave point to Col. M. O'Gorman's reference to the need for more scientific knowledge in high quarters at the Air Ministry. He pointed out that fighting now depends on technical complications beyond the understanding of military commanders, and that dependence on their opinions alone will necessarily lead to an unbalanced policy. The need for such remarks was shown by Lord Gorell when he said: "I do not speak in the least degree as a technical expert; probably in the position which I happen to hold it would be a disadvantage to pretend to any degree of technical qualifications." Col. O'Gorman was unable to see why technical and scientific knowledge should be a disqualification in a Minister.

During the discussion on civil transport much reference was made to the need for research, but in the afternoon the theme was research and yet more research. A deep impression on the conference was produced by Sir Richard Glazebrook's references to R38. Lord Gorell's paper contains the passage: "Since the decision of the Dominion Premiers was taken, the conquest of the air has suffered one of the greatest disasters of its history in the terrible accident to R38. It ought to be decisively said that the disaster has not affected, and will not affect, the belief in the future of airships. We are not so faint-hearted a race as to allow ourselves to be deterred even by such an event; *it is the toll that Nature inevitably exacts* from those who seek to probe her secrets—and it has been paid."

Sir Richard Glazebrook asked: "Was the loss of the airship R38, with its crew of officers, technicians, and men, necessary? Was it one of those dreadful and seemingly inevitable incidents in the evolution of a new craft?" and answered his questions by saying that "knowledge existed from experiments in the air tunnels which would have enabled the collapse of the ship to be foretold." The knowledge had not been applied because of a gap between model and full-scale experiments; attempts by the designers and the Aero-

nautical Research Committee to obtain facilities for full-scale experiment on R31, R32, and R33 had failed. He urged as a partial atonement for the sacrifice of the lives of brave men that the remnants of the airship fleet should be devoted to correcting, by full-scale experiments, the knowledge given by model experiments.

The situation with regard to aeroplanes was also said to be unsatisfactory. Prof. L. Bairstow pointed to the prevalence of accidents in aviation, the risks of flying being so great that life insurance companies are not prepared to cover them in a standard policy. This abnormal rate was attributed in part to a number of defects not needing more knowledge for their remedy. The failure of rubber joints in petrol pipes and the breakage of ignition cables were given as instances of easily remediable defects. The danger of such imperfections comes from the necessity for landing at once, when the engine ceases to turn, in country which is often unsuitable. So soon as an aeroplane can take the air it leaves the designer for the user, and its minor defects have not then developed. New design might be encouraged by placing responsibility for such matters on the designer, and not on an Air Ministry staff.

Other causes of failure in flight were said to need more knowledge before they could be removed. All aeroplanes are tricky at low speeds, and it does not accord wholly with fact to attribute an accident to "bad piloting causing the aeroplane to lose flying speed near the ground." Important research work is here called for, the conduct of which may be hindered by an unsuitable organisation as much as by lack of funds. It is reported that the Secretary of State for Air has the matter of the reorganisation of the Air Ministry under review, and has afforded the council of the Royal Aeronautical Society an opportunity for expressing the scientific and technical view of essential requirements for the carrying on of research. It is encouraging to note that Lord Gorell told the Air Conference that "success in the air, whether Service or civil, must depend primarily upon constant scientific research," and that the report of the Geddes Economy Committee, whilst asking for a reduction on the vote for experiment and research, accepts that view.

If research and care in design can reduce the accidents now occurring to one-third of their present amount—a very moderate estimate of early possibilities—the saving of money on flying risks, replacement of aircraft, etc., will very greatly exceed the cost incurred. The position is unusual in the fact that the effects of research on the final product are so clearly seen; such a state is largely due to the infancy of the science, but an important additional element arises from the unparalleled degree of freedom of the motion of aircraft as compared with that of other vehicles.

The Grain of the Photographic Plate.

THE unit of the photographic plate is the single grain of silver salt as it exists in the sensitive film. It is natural, therefore, that after many years and much labour had been devoted to the properties of sensitive films as films, attention should be turned to the unit. A great deal of work has already been done in this direction, but many problems, some of which seem to be of an elementary character, remain to be solved.

On Tuesday, February 14, Prof. The Svedberg, of Upsala, communicated to the Royal Photographic Society two papers containing important results that he has obtained. It is customary in such investigations to dilute the emulsion and so produce a film that contains only a single layer of grains. The characters of the grains are registered by photomicrography, using apochromatic objectives of the maximum practical aperture. As the photography of the grains before treatment must not affect their sensitiveness, Prof. Svedberg used a very deep red light and Ilford special rapid panchromatic plates. After exposure and development the plate may be photographed again, then either the metallic silver produced or the unaffected grains may be dissolved away, as desired, to facilitate the examination of the remainder.

Evidence in favour of the view that the halide grain is either wholly reducible (developable) or not reducible at all is accumulating, and this Prof. Svedberg finds definitely to be the case. By dissolving away the silver grains nothing whatever was left of them, except to the extent of about 1 per cent. of the thousand or so grains observed, which showed traces of incomplete reduction (development).

This independency of the grains is further proved by the unchanged appearance of the undeveloped grains and their unchanged sizes as measured. This holds even when the film is partly solarised by a strong light, when the grains are separated by only 1μ, and whether ferrous oxalate or metol-hydroquinone developer is employed. The author intends to try other conditions to see if, as appears to be the case, these results are general, and that feeding of the reduced silver grains at the expense of the undevelopable grains does not, in fact, take place.

In Prof. Svedberg's second communication he suggests that the larger and the smaller grains in one and the same emulsion are equally sensitive and "are built up of the same kind of light-sensitive material—just as if they were fragments of different sizes from one homogeneous silver bromide crystal." He assumes that by exposure (light action) "developable centres" are produced, and shows experimentally that the distribution of these "centres" takes place according to the laws of chance, so that there is no need to assume a superior sensitiveness of those grains that are made developable. The author is to be congratulated on using the term "centre," which expresses all that is known and is non-committal, rather than "nucleus." Nuclei have been shown to serve, but the crystallisation of sugar on strings is not evidence of the presence of strings wherever sugar crystallises. This by the way.

The present writer in 1911 (Journ. Roy. Phot. Soc., p. 159) showed that by stopping development at a very early stage it was possible to get particles of silver too small to be visible microscopically. They were shown to be present by the colour imparted to the film, and were further demonstrated and measured by adding mercury to them in known and progressive proportions and measuring the enlarged particles. Prof. Svedberg by stopping development at a little later stage gets particles that are just definitely visible microscopically, and shows photographically the relation of these to the original grains of silver haloid. He thus demonstrates that "centres of development" are produced by exposure. A single developable grain may contain one or more (so far up to four) of these "centres." He treats also of other matters, such as the effect of Röntgen rays when used instead of ordinary light.

C. J.

Building Materials and Heat Insulators.

THE Department of Scientific and Industrial Research has issued two special reports on floors and thin walls, the result of work undertaken by an *ad hoc* Building Materials Research Committee appointed to investigate new materials and constructional methods in connection with housing schemes (H.M. Stationery Office, 1*s*. 3*d*. net and 6*d*. net respectively). Some eight types of floors were dealt with, comprising hollow tiles, brick and tile, reinforced concrete, ash concrete, and ordinary wood joists. Suitable sections or units of these floors were erected and tested for carrying capacity to destruction. The results are summarised in tabular form, showing the weight of the floor, load carried, deflection, breaking load, age on testing, elastic limit, and so on. These results are also plotted diagrammatically, and drawings are given showing the construction of each floor to scale. The ash concrete proved weak, and the ordinary joisted floor, though possessing obvious disadvantages from some aspects, appeared to hold its own in the matter of strength. The experiments on thin walls included the testing of brick and concrete blocks and slabs and coke-breeze materials. Consistent results showed that the crushing strength of the walls varied from 67 to 83 per cent. of that of cubes of the materials respectively employed. Lengths of wall of 14 in. and 3 ft. 6 in. and 2⅝ in. to 4½ in. thick were dealt with. These strips were 8 ft. 6 in. high, and the horizontal pull necessary to make the wider strips collapse was measured. The materials built in lime mortar on account of early failure under test give rise to criticism of lime as a binding agent, but surely the behaviour of walls so built after only twenty-four days cannot be fairly compared with that of similar walls built in cement which sets in a day or two. Lime was used in all our national buildings until comparatively recent years; it is cheaper in actual cost and labour than cement, and its wider use merits revival. These experiments are valuable and interesting; it has to be remembered, however, that the country builder usually fears new methods, and is apt to put unduly high prices on unknown forms of construction.

The fifth special report of the Food Investigation Board, issued by the Department of Scientific and Industrial Research, consists of an account of experiments on heat insulators suitable for use in cold stores. The work has been carried out at the National Physical Laboratory by Dr. Ezer Griffiths, and so far has been devoted to the determination of the thermal conductivity of a number of materials adapted to low-temperature insulation. In the experiments a warm surface, consisting of a metal plate electrically heated, was maintained at a steady temperature and placed opposite to a similar plate cooled by brine circulation, the material under test filling the space between the two plates. Special precautions were taken to eliminate errors arising from edge effects in the warm plate and air convection in the material, and when a steady temperature had been attained in both plates the heat passing through the lagging was deduced by measuring the watts furnished to the warm plate. The results obtained show that the conductivity in C.G.S. units for slab cork is 0·00011; granulated cork, 0·00011 to 0·00019; slag wool, 0·000102; and dry charcoal, 0·000122. A number of other substances giving higher values were also tested, and mention is made of a cellular form of rubber which from preliminary tests appears to be superior to any other material examined, its conductivity being about 0·000085. As an appendix to the report, a description is given of the apparatus devised by Dr. Griffiths for determining the specific heats of the materials under notice. Although other factors, such as moisture absorption and liability to organic growths, have to be taken into account in choosing a lagging for a cold store, the figures obtained by Dr. Griffiths should prove of much practical value to those engaged in the refrigerating industry.

Industrial Fatigue.

THE Industrial Fatigue Research Board, which has recently been reconstructed as an advisory body under the Medical Research Council, is to be congratulated upon the publication of two highly valuable and most interesting reports. These are doubtless a legacy to it from the older Board the wider sphere and greater liberty of action of which were recently brought to an end by the Treasury under the pretext of economy. They are published by H.M. Stationery Office at 1*s*. and 2*s*. respectively, Report No. 12 being on vocational guidance and Report No. 15 on motion study in metal polishing. The former of these reports, written by Mr. B. Muscio (who has since accepted a professorship in the University of Sydney), gives a detailed review of the literature on vocational selection. The list of nearly sixty books and papers at the end of the report indicates the diligence which the author has brought to bear on his task. The report is divided into three sections: (1) introductory, (2) summary of special investigations, and (3) future investigations. The second section, filling forty-two of the fifty-seven pages, contains a most able and critical account of the psychological tests that have been applied to clerical, engineering, and metallurgical occupations, music, printing, salesmanship, telegraphy, telephone exchange work, transport work, war experiments, etc. Prof. Muscio indicates in his last section the wide field which is now open for future investigations conducted on a broader scale and on a more systematic basis than hitherto.

Not less valuable is the Board's Report No. 15 on motion study in metal polishing by Messrs. E. Farmer and R. S. Brooke. These investigators prove very conclusively what an enormous wastage of effort now occurs in the "buffing" (spoon and fork polishing) trade owing to the lack of a systematic course of training for newly entering workers. They indicate the principles on which such a course should be based, and give data derived from the actual application of those principles, which "prove conclusively that a beginner, given adequate training, can become an expert dollier within a very few days, but left to herself, without proper instruction, she probably will never become highly skilled, and will continue all her life to waste her energy in unnecessary and unproductive movements." The influence of fatigue was ingeniously studied by means of a recording wattmeter which they applied to the machines employed for removing scratches and other imperfections from spoons and forks. It was found that as towards the end of the day the girls' output diminished and their

fatigue increased, they tended to give more vigorous and more numerous strokes, to pause longer between each stroke, and to take a longer time over each stroke. In other words, Messrs. Farmer and Brooke prove that the tired "rougher" is "not only working slower than when she is fresh. but is also expending her energy extravagantly."

University and Educational Intelligence.

London.—The Franks research studentship in archæology, value 100*l.* for one year, is offered. Applications must reach the Academic Registrar, the University of London, South Kensington, S.W.7, by, at latest, March 2.

Sheffield.—The council of the University has made the following appointments:—Mr. Douglas Hay to be professor of mining; Mr. A. J. Saxton, assistant lecturer in physics; Mr. L. W. Cole, assistant lecturer and demonstrator in botany; Mr. H. W. Southgate, lecturer in pharmacology; Dr. E. F. Finch and Mr. V. Townrow, assistant curators of the Pathological Museum; and Dr. A. G. Yates, demonstrator in medical pathology.

Last year the Civic Education League organised a very interesting Easter visit to Belgium for the purpose of civic study. This year a similar visit to Holland is being arranged. Anyone interested in civic studies may join the party, and early application to Miss Margaret Tatton, secretary, Civic Education League, Leplay House, 65 Belgrave Road, S.W.1, should be made. Members of the party will have special facilities for first-hand contact with the work and *personnel* of the chief social and economic institutions of the country.

The annual prize distribution at the Sir John Cass Technical Institute, Aldgate, E.C.3, was held on Wednesday, February 8, when the prizes were distributed by Prof. William Rothenstein, principal of the Royal College of Art. The chairman of the governing body, the Rev. J. F. Marr, in giving a summary of the work of the institute during the past session, stated that the increase in the number of students had been more than maintained, and that the capacity of the institute, especially in the science departments, had been taxed to the utmost. Twenty students had been engaged in research work during the session, and the total number of investigations published from the institute had now reached 115. The Department of Petroleum Technology, which was initiated at the commencement of the present session, is one of the institute's most important developments, and there were already 150 students in attendance. Representatives of the industry have acted as a consultative committee to advise the governors in respect to the courses of study which have been provided, and the chief oil companies of the London area have given generous support towards the equipment and maintenance of the department. In the course of an address on "Education and Industry" Prof. Rothenstein said he regarded every kind of education as something in the nature of a pursuit after truth. Whereas there was much lip-homage to science and art and the crafts by our merchant princes and captains of industry, these employers did not have the same faith in them as their employees. Commercial men in past civilisations somehow knew how to ask for the best, but that was not true of our own civilisation. What we required was a standard of commerce which knew how to utilise what was best in the arts and sciences, for he refused to believe that people, in general, did not value that which was good and beautiful in production.

Calendar of Industrial Pioneers.

February 16, 1890. William Jarvis McAlpine died.—Trained under Jervis, the chief engineer of the Delaware and Hudson Canal, McAlpine became State Engineer for New York, and was also State Railroad Commissioner. At the request of the Austro-Hungarian Government he prepared plans for the improvement of the Danube. He was the first American to become a member of the Institution of Civil Engineers, and in 1886 was president of the sister institution in the United States.

February 18, 1888. Thomas Turner Tate died.—In conjunction with Sir William Fairbairn, Tate was the author of memoirs on the vapour tension of superheated steam and on the strength of materials in relation to the construction of iron ships, and was the inventor of the double piston air-pump. For some years he was mathematical master at Battersea Training College, and was known for his educational works.

February 19, 1816. Jean Pierre François Guillot Duhamel died.—An early student at the Ecole des Ponts et Chaussées, Duhamel accompanied Gabriel Jars in his extended industrial tour throughout Europe, and on his return to France did much to improve the manufacture of steel. He afterwards became Government Inspector of Forges and Furnaces, a professor of metallurgy at the Ecole des Mines, and a member of the Paris Academy of Sciences.

February 20, 1825. Joseph Marie François Cachin died.—One of the most distinguished French civil engineers of his day, Cachin was intimately connected with the improvements of the harbour of Cherbourg, and in 1820 published his "Mémoire sur la digue de Cherbourg comparée au breakwater, ou jetée, de Plymouth."

February 20, 1826. Matthew Murray died.—With Fenton and Wood, Murray founded a mechanical engineering works at Leeds which became one of the rivals of Boulton and Watt. The firm built flax-making machinery and constructed some of the earliest Blenkinsop locomotives, and Murray is generally credited with the invention of the short D-slide valve for steam engines.

February 20, 1913. Sir William Arrol died.—The builder of many famous bridges, Arrol between 1882 and 1887 reconstructed the viaduct over the Firth of Tay, and between 1883 and 1890 built the Forth Bridge. This bridge, designed by Fowler and Baker, has always been regarded as one of the greatest engineering structures in the world. With a total length of 8295 ft., of which the three cantilevers account for 5349 ft., the bridge contains 51,000 tons of steel, while the towers rise to a height of 360 ft. and the line is carried 150 ft. above the water at high tide. Arrol was knighted at the opening of the bridge by Edward VII.

February 21, 1888. George Henry Corliss died.—The greatest steam-engine builder of America, Corliss about 1848 entered into partnership with Nightingale at Providence, Rhode Island. Adopting the trip gear of Sickells, he brought out the Corliss form of steam engine, which on account of its improved economy and regular turning movement became known all over the world.

February 21, 1912. Osborne Reynolds died.—For nearly forty years professor of engineering at Owens College, Manchester, Reynolds made many investigations of importance to engineers and shipbuilders, such as those on screw propulsion, the flow of liquids, the condensation of steam, the transmission of heat, and lubrication. He was the inventor of the compound turbine.

E. C. S.

Societies and Academies.

London.

Royal Society, February 9.—Sir Charles Sherrington, president, in the chair.—Sir J. Alfred **Ewing**: The atomic process in ferromagnetic induction. In the old model representing the process of ferromagnetic induction, the Weber elements or ultimate magnetic particles were represented by pivoted magnets the alignment of which, in the absence of an impressed field, was determined by the forces which they exerted on one another. The model is unsatisfactory; when the range of stable deflection is sufficiently narrow the stability becomes too great. In the new model the idea of magnetic control is retained, with a Weber element in each atom, but the controlling force is supposed to be exerted between the electrons of the atom itself, namely, between the shell, which is held more or less fixed by its relation to neighbouring atoms, and an inner electron system which constitutes the Weber magnet. The control depends on the difference between two nearly equal opposing forces; this characteristic permits the model to combine a sufficiently weak control with a narrow range of stable deflection. In one model considered the structure is based on the grouping of electrons suggested by Hull in connection with his X-ray analysis of iron crystals; in another the electron orbits are assumed to have the nucleus of the atom at their common focus.—J. W. **Nicholson**: Problems relating to a thin plane annulus. Only first approximations of solutions of problems relating to a thin plane annulus appear to have been used hitherto. Higher approximations have now been obtained, and the actual difference of radii of the circles bounding the annulus is of comparatively small significance in such magnitudes as the electrical capacity of the annulus. The whole investigation is carried to the second order of significance by treating the annulus as a special case of the elliptic anchor ring, but it can be extended. The convergence of such approximate solutions appears to be analogous to the degree of convergence found by Lord Rayleigh in certain solutions of problems of vibration of discs in which eccentricity is taken into account.—T. H. **Havelock**: The effect of shallow water on wave resistance. An analysis of the wave resistance of a surface pressure symmetrical round a point and moving over the surface of deep water is extended so as to include the effect of finite depth of water. The wave resistance is given by a definite integral which is evaluated by numerical and graphical methods. The cases intermediate between deep water and shallow water show the effect of limited depth in lowering the principal wave-making velocity and in increasing the effects near the velocity of the wave of translation.—R. H. **Fowler** and C. N. H. **Lock**: The aerodynamics of a spinning shell. Pt. 2. Of the shells fired from two guns giving different degrees of axial spin, those fired from the gun giving the more rapid spin were all stable, most of the others being unstable, as shown by the larger yaw developed. For yaws up to 35° a solution of the equations of motion can still be obtained in elliptic functions which proves adequately general.—F. B. **Pidduck**: The kinetic theory of a special type of rigid molecule. The methods of Chapman and Enskog in the kinetic theory of gases are applied, with modifications, to a type of rigid molecule to discover how viscosity is affected by energy of rotation, and the relative transport of translational and rotational energy in thermal conduction. The molecule model is considered as a sphere which grips at each collision and rebounds without dissipation of energy. The results support Eucken's views on Chapman's constant f for polyatomic gases.—J. E. **Jones**: The velocity distribution function and the stresses in a non-uniform rarefied monatomic gas. From Boltzmann's equation a symbolic solution of the velocity distribution function is obtained; from the new equation, by an analogous treatment, the exact nature of the function is deduced. The rate of change of molecular properties by collision follows more directly from this equation than from that used by Maxwell. To illustrate the present method, the results obtained by Chapman and Enskog for a normal gas are calculated anew. The treatment is extended to a rarefied gas and expressions are obtained for stresses due to non-uniformity of temperature. The special Maxwellian model is considered and Maxwell's result confirmed. The molecular model of a gas consisting of rigid elastic spheres is then considered in detail. The numerical coefficient in this case differs by about 20 per cent. from that of the Maxwellian gas.—H. **Bateman**: The numerical solution of integral equations. An approximate solution of an integral equation of Fredholm's type is obtained by using an approximate representation of the kernel by means of a double series of known functions. One such series is written down immediately in the form of a determinant, and the solution of the integral equation with the approximate kernel is also written in the form of a determinant. The kernel of the integral equation can also be represented approximately by a polynomial.—W. B. **Hardy** and Ida **Doubleday**: Boundary lubrication: The paraffin series. The lubricating properties of normal paraffins and their related acids and alcohols have been studied under the conditions of boundary friction. Amonton's law, that friction varies as the loads and is independent of the areas, is rigorously true for the same bearing surfaces and lubricants. The friction is independent of the quantity of lubricant present. It is a linear function of molecular weight, so that $\mu = \text{friction} \div \text{load} = a - b\text{M}$, where M is molecular weight and b a pure function of chemical constitution; the slope of the curve is greatest for acids, and sensibly the same for paraffins and alcohols. Changing from one acid to another shifts the curves parallel to themselves, so for the same chemical series a is a pure function of the nature of the solid faces. Each solid face contributes one-half of a, and each molecule of lubricant furnishes a constant quantity to the total effect independently of the total number of molecules present.

Aristotelian Society, January 16.—Dr. F. C. S. Schiller, president, in the chair.—H. J. **Paton**: Plato's theory of εἰκασία. In Plato's account of the Line and the Cave in the "Republic" he distinguishes two sub-divisions of opinion (εἰκασία, or intuition, and πίστις, or belief) and two sub-divisions of knowledge (διάνοια, or mathematical reasoning, and νόησις, or philosophical reasoning). This must be understood as implying a difference of objects in each of the four sub-divisions, just as the objects of opinion and knowledge are different—the changing individuals as opposed to the unchanging universals. The parallelism or analogy between the objects of the two main divisions and those of the sub-divisions is meant to be taken seriously throughout. In particular, the objects of the εἰκασία, or intuition, are the many appearances whether given in what we call sense or memory or imagination, from which we pass to the objects of πίστις, or belief—the solid bodies of the ordinary consciousness and of science, things relatively permanent and relatively intelligible in comparison with their many appearances, although changing and unintelligible in comparison with the really permanent and really intelligible εἴδη, or universals. It is a complete error to

regard εἰκασία and its objects as of no metaphysical importance, and an understanding of the nature of this section is necessary if we are to grasp Plato's general theory of knowledge. Even Plato's theory that art must be classified under this first cognitive activity of the spirit is in its essence sound, in spite of the fact that some of the conclusions which he derived from it were mistaken.

Association of Economic Biologists, January 27.—Sir David Prain, president, in the chair.—E. P. **Stebbing**: The importance of scientific research in forestry and its position in the Empire. In India a research institute was formed at Dehra Dun in 1906, and the fully equipped building completed by 1914. It has now become necessary to decentralise research work to some extent, and a fine institute is already in existence at Coimbatore, in Madras. Elsewhere in the Empire, with the exception of Canada and at home, the forest services are only in the initial stages of the introduction of the work. A start should be made in the branches of forest botany and forest economics. At home a well-equipped research institute is most urgently needed which would work in collaboration with the educational centres the staffs of which have time available to devote to research work. Until such a research institute is established full use should be made of centres the equipment of which is adequate for carrying on research on the lines which the Forestry Commission may suggest.

Physical Society, January 27.—Sir William Bragg in the chair.—T. H. **Littlewood**: The diffusion of solutions. An optical method is described for finding the concentration at various depths in a diffusing solution. The solution is contained in a closed vessel, the top and one side of which are of glass. On the glass side is a vertical scale. This vessel is immersed in water containing a mirror which can be rotated, and the position of which is read on a graduated scale by a telescope which carries a horizontal wire illuminated by sodium light. The mirror is adjusted so that the image of the wire, after twice passing through the liquid, is seen on the cross wires of the telescope, and the reading on the vertical scale is also observed. The concentration can be determined at different depths with an accuracy of about 0·05 gr. per litre. From a series of measurements at different times the coefficient of diffusion can be calculated. Sufficient data can be obtained in less than a day.—H. R. **Nettleton**: A special apparatus for the measurement at various temperatures of the Thomson effect. The short wire under test (S.W.G. 18) passes through electrical heaters which may quickly be brought to, and maintained at, steady temperatures differing by some 50° C. over the range 20° C. to 250° C. A short coil of the finest double silk-covered copper wire (S.W.G. 44) acts as the Thomson-Joule heat detector.—J. J. **Manley**: A defect in the Sprengel pump: its causes and a remedy. A plan whereby the limitations and irregularities of the Sprengel pump resulting from the presence of air skins upon the interior surfaces may be made negligible is described. The efficiency of the new pump is superior to that of the older forms, and appears to be constant.

DUBLIN.

Royal Dublin Society, January 24.—Mr. G. Fletcher in the chair.—H. H. **Poole**: Some notes on the distribution of activity in radium therapy under different conditions of screening. Tests were made of the screening effect of various materials on the complex radiation emitted from a thin-walled emanation tube. From these the activity at various depths in the tissues were calculated for several arrangements of surface applications and for emanation needles.

EDINBURGH.

Royal Society, January 9.—Prof. F. O. Bower, president, in the chair.—R. A. **Houstoun**: A new method of investigating colour-blindness, with a description of twenty-three cases. The method was based on Maxwell's colour diagram, and consisted in testing the power of discriminating between contiguous tints of colour as the tint was varied continuously by stages from, say, red to green by an increasing admixture of green with red. The results for each observer were represented by contour lines on the triangular colour diagram. The ability of the observer to discriminate between any pair of colours could be seen from his diagram at a glance, irrespective of the terminology of any particular theory. More than 1400 students of Glasgow University had been tested during the last four years. All the cases of colour-blindness investigated seemed to be trichromatic in Maxwell's sense, not dichromatic as stated in text-books. Also, two observers who confused ordinary greens and reds were found, on the whole, to have quite as good a power of discriminating colour as the normal. Their trouble was apparently due to their colour-vision being extra sensitive to changes of wave-length in the green part of the spectrum, and not sensitive enough to changes of wave-length in the yellow.—W. Gordon **Brown**: The Faraday-tube theory of electromagnetism and other notes. The author met his death in France in 1916 at the age of twenty-one, and these papers were written in 1915–16 while he was convalescing after his Gallipoli experiences. He had just finished school in 1914, and he joined the Forces immediately war was declared. In the principal paper he established, on the assumptions of moving tubes of electric force, the equations of the electromagnetic field, and in a shorter quaternion investigation he worked out certain results on the hypothesis that the mass operator which changes velocity to momentum is a linear vector function. A few months before his death he was treating the problem of the tubes of force along the lines of the four-dimensional analysis developed by Minkowski, and communicated his results in a letter written to Prof. Whittaker.—T. Bedford **Franklin**: Some simple experiments on the colloidal content of soils. The mechanical analysis of a soil is no guarantee of its physical behaviour, for although the soil colloids are mainly contained in the finer fractions, yet the colloidal content of these fractions, as shown by analysis, can vary over a very large range. The paper described simple experiments for estimating the colloidal content. Thus a soil is probably highly colloidal if (1) it takes up a high percentage of water on the dry weight of the soil before reaching "maximum plasticity"; (2) its rate of evaporation declines slowly with diminishing water content; (3) it freezes well below 0° C.; (4) it takes up, after drying or freezing, much less water before reaching "maximum plasticity" than in its natural condition; and (5) it absorbs and retains for a long time farmyard or artificial manure.

PARIS.

Academy of Sciences, January 30.—M. Emile Bertin in the chair.—C. **Lallemand**: The comparative advantages of the hexagonal abacus and the abacus with aligned points.—C. **Moureu** and C. **Dufraisse**: Auto-oxidation. The anti-oxidisers.—G. **Gouy**: The pressure in magnetised or polarised fluids.—M. Maurice d'Ocagne was elected a free academician in succession to the late M. J. Carpentier.—T. **Varapoulos**: A theorem of M. Montel.—A. **Angelesco**: The zeros of certain functions.—A. **Cahen**: Differential equations of the first order with fixed critical points.—M. **Auric**: The development as a continued fraction of algebraical numbers.—R. **Jacques**: Surfaces such that the axes

of the osculating circles with one family of lines of curvature belong to a linear complex.—E. **Belot**: The periodicity and the movement of the sun-spots in latitude explained by the pulsation of the nucleus. Assuming that the dense nucleus of the sun (barosphere) has a pulsation with a period of eleven years, the consequences are worked out and give an explanation of the currents from north to south in the perisphere, observed, but not explained, by Oppolzer; the movement of the spots towards the equator (Spörer); and the displacement of the latitude of the maximum number of spots, which, according to Faye, should be in latitude 37° 38′, and is, in fact, about 17°.—H. **Chaumay**: The measurement of insulation resistance by the method of accumulation.—M. **Dufour**: The relation between aberration and astigmatism for a point situated on the axis of a centred optical system.—J. **Rey**: Range obtained by a beacon light of great power fitted with metallic reflectors. This light is installed on the Island of Galiton, north-west of Bizerta, and is 165 metres above sea-level. The calculated range was 30 miles. It can be frequently seen from Tabarka, 33 miles away, and in clear weather at Ras-Enhelah (41 miles).—H. **Weiss** and P. **Henry**: The influence of temperature on the velocity of interpenetration of solids. The alloy studied was silver containing 14 per cent. of antimony; the results are given in a series of curves.—E. **Darmois**: Two new molybdo-malates of ammonium. Gernez has shown that the rotatory power of malic acid undergoes considerable variation when increasing quantities of ammonium molybdate are added to the solution. From a study of the rotation of solutions of malic acid and ammonium molybdate two definite compounds, $MoO_3 \cdot 2C_4H_6O_5 \cdot 2NH_3$ and $MoO_3 \cdot 2C_4H_6O_5 \cdot 4NH_3$, were indicated, the first being the more stable. The isolation of these two compounds is described.—MM. **Seyewetz** and **Vignat**: The action of sodium sulphite on nitrobenzene. Nitrobenzene is reduced by a boiling 10 per cent. solution of sodium sulphite. The main product of the reaction is *p*-amidophenol sulphonic acid.—C. **Jacob**: The structure of North Annam to the south of Thanh Hoa.—F. **Blanchet** and E. **Chagny**: New observations on the dislocation of the Montagne de la Bastille, near Grenoble.—C. **Corroy**: Some Neocomian fishes of the Haute-Marne and the Meuse.—L. **Joleaud**: The area of dispersion of Dyrosaurus, a fossil crocodile from North-West Africa.—A. **Boutaric**: Observations carried out on Mont Blanc. Details of polarimetric and actinometric observations made hourly, between 7 a.m. and 6 p.m., at the Vallot Observatory between July 31 and August 7, 1921.—L. **Gentil**: The climatology of Morocco. In the absence of extended meteorological observations the study of the vegetation furnishes a valuable guide to climatic conditions. The rainfall chart in eastern Morocco of M. Augustin Bernard cannot be accepted without reserve.—P. **Schereschewsky** and P. **Wehrlé**: The signification of cirrus clouds in the prediction of weather. Cirrus clouds have often been considered as indicating the approach of rain; the authors show that the cloud system must be studied as a whole. Cirrus clouds are always indications of the proximity of a cloud system, but it does not necessarily follow that the system will pass over the observing station. It is necessary for the meteorologist to be able to determine the position of the cloud system in relation to the observing station, its direction of motion, and its velocity of displacement, before utilising cirrus clouds as a means of weather prediction.—Mlle. C. **Veil**: The relation between the chlorine index and the nitrogen content of plant-soil. The chlorine index is given by the amount of active chlorine absorbed by the soil from a solution of sodium hypochlorite. It is shown that there is a relation between this figure and the amount of nitrogen in the soil.—P. **Dangeard**: The origin of the vacuoles at the expense of the aleurone grains during the germination of the Graminaceæ.—W. **Kopaczewski**: Surface tension and narcosis. As a general rule narcotics and anæsthetics lower the surface tension of the blood-serum, and there is a parallelism between the amount of lowering and the narcotic power. There are exceptions, morphine being the most notable.—R. **Jeannel**: The variation of the copulating organs in the Coleoptera.—L. **Léger** and E. **Hesse**: Microsporidia resembling bacteria in form, and an attempt at a systematic classification of the group.—Mme. Anna **Drzewina** and G. **Bohn**: The phenomena of auto-destruction and auto-agglutination in the Convoluta.—M. **Aron**: The morphological signification of the endocrinian glandular tissue of the testicle in the crested triton.

SYDNEY.

Royal Society of New South Wales, December 7, 1921.—Mr. E. C. Andrews, president, in the chair.—C. A. **Sussmilch**: The geology of the Gloucester district. The strata of the Gloucester district (N.S.W.) belong to the Devonian Carboniferous and Permo-Carboniferous periods. During the Devonian period a thick series of shales, radiolarian cherts, and tuffs was laid down on a sea-floor. Submarine volcanic activity and important crustal movements took place during and at the close of this period. At the beginning of the Carboniferous period (Burindi stage) the region was under relatively shallow water. Long-continued slow subsidences allowed of the depositing of a very thick series of shales, limestones, conglomerates, and tuffs, aggregating 12,000 ft. in thickness. Later an uplift took place, and during the Kutting stage which followed volcanic activity was the most striking feature. The land flora (Rhæopteris, etc.) at this time consisted largely of ferns. Towards the close of the Permo-Carboniferous period a subsidence began which led to the formation of a large shallow lake. At intervals conditions became stable, the lake became a swamp covered by dense vegetation (the Glossopteris flora), and during these periods coal-seams were formed. There are at least eight coal-seams in the Gloucester district, the largest of which is 32 ft. thick. At the close of the Permo-Carboniferous period the region was subjected to intense folding forces, forming big mountain ranges. Since then there have been a succession of uplifts, the last of which took place at the end of the Tertiary period, and produced a tableland 2000 ft. in altitude.—O. U. **Vonwiller** The conduction of electricity in molybdenite.—G. J. **Burrows** and E. E. **Turner**: The preparation of certain ferrioxalates.—J. H. **Maiden**: An additional blue-leaf stringybark. A blue-leaf stringybark already described is *E. laevopinea*, R. T. Baker; the new species is more closely allied to *E. Blaxlandi*, Maiden and Cambage, and *E. capitellata*, Sm. It is a large tree, with sessile heads of small compressed spheroid fruits, which is confined, apparently, to New South Wales.—W. L. **Waterhouse**: The production in Australia of the æcidial stage of *Puccinia graminis*, Pers. Inoculations on barberry shoots with rust on wheat grown at Glen Innes, N.S.W., gave numerous infections from which æcidiospores were used to reinfect wheat.—A. R. **Penfold**: The essential oil obtained of the leaves of *Doryphora sassafras*, Endlicher. The yield of oil from leaves of the New South Wales sassafras tree was about 1 per cent., and it possessed the fragrance characteristic of sassafras oils. The principal constituents identified are safrol, camphor, pinene, sesquiterpenes, eugenol, and alcoholic bodies.

Diary of Societies.

THURSDAY, FEBRUARY 16.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. A. G. Perkin: Dyeing: Ancient and Modern (1).

ROYAL SOCIETY, at 4.30.—Prof. L. Hill, D. H. Ash, and J. A. Campbell: The Heating and Cooling of the Body by Local Application of Heat and Cold.—Prof. J. B. Cohen, C. H. Browning, R. Gaunt, and R. Gulbransen: Relationships between Antiseptic Action and Chemical Constitution, with Special Reference to Compounds of the Pyridine, Quinoline, Acridine, and Phenazene Series.—D. T. Harris: Active Hyperæmia. —B. B. Sarkar: The Depressor Nerve of the Rabbit.—Prof. A. Lipschütz, Dr. B. Ottow, C. Wagner, and F. Bormann: The Hypertrophy of the Interstitial Cells in the Testicle of the Guinea Pig under Different Experimental Conditions.

CHINA SOCIETY (at School of Oriental Studies), at 5.—Miss E. G. Kemp: Some Aboriginal Tribes in China.

LINNEAN SOCIETY OF LONDON, at 5.—Prof. R. R. Gates: The Inheritance of Flower Size in Plants.—W. Dallimore: Exhibition of Dwarf Trees, showing Wind Effect on Rocks at Llandudno.—J. L. North: Acclimatisation of the Soja Bean, *Glycine Soja*.

ROYAL SOCIETY OF MEDICINE (Dermatology Section), at 5.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.30.—Sqdr.-Ldr. C. F. A. Portal: Methods of Instruction in Aeroplane Flying.

INSTITUTION OF MINING AND METALLURGY (at Geological Society of London), at 5.30.—J. M. Bell: The Occurrence of Silver Ores in South Lorrain, Ontario, Canada.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—F. P. Whitaker: Rotary Converters, with Special Reference to Railway Electrification.

INSTITUTION OF AUTOMOBILE ENGINEERS (London Graduates' Meeting), at 8.—L. F. Watson: Mechanical Efficiency.

CHEMICAL SOCIETY, at 8.—A. Lapworth: A Theoretical Derivation of the Principle of Induced Alternate Polarities.—W. O. Kermack and R. Robinson: An Explanation of the Property of Induced Polarity of Atoms and an Interpretation of the Theory of Partial Valencies on an Electronic Basis.

SOCIETY FOR CONSTRUCTIVE BIRTH CONTROL AND RACIAL PROGRESS (at Essex Hall, Essex Street, W.C.2), at 8.—E. B. Turner: Sex Relationships.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (at 11 Chandos Street, W.1), at 8.15.—Major F. W. Cragg: Relapsing Fever in India.

SOCIETY OF ANTIQUARIES, at 8.30.

FRIDAY, FEBRUARY 17.

GEOLOGICAL SOCIETY OF LONDON (Anniversary), at 3.—Presidential Address.

ROYAL SOCIETY OF MEDICINE (Otology Section), at 5.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof Swale Vincent: A Critical Examination of Current Views on Internal Secretion (Arris and Gale Lecture).

INSTITUTION OF MECHANICAL ENGINEERS (Annual General Meeting), at 6.—A. T. Wall: Electric Welding applied to Steel Construction, with Special Reference to Ships.

BRITISH ELECTRICAL DEVELOPMENT ASSOCIATION (at Chartered Institute of Patent Agents, Staple Inn Buildings, W.C.2), at 7.30. —H. Harrison: Salesmanship in Relation to Electric Lighting.

JUNIOR INSTITUTION OF ENGINEERS (at Caxton Hall), at 8.—W. J. Leaton: Water Purification for Boiler Feed Purposes.

SOCIÉTÉ INTERNATIONALE DE PHILOLOGIE, SCIENCES ET BEAUX-ARTS (Celtic Section) (at 8 Taviton Street, W.C.1), at 8.—Dr. W. J. E. Scott: The Mines of El Dorado: an Historical Account of the Maritime Trade of Spain with Ireland, 2000 to 700 B.C. (2).

ROYAL SOCIETY OF MEDICINE (Electro-therapeutics Section), at 8.30. —Dr. G. W. C. Kaye: Radiology and Physics (Mackenzie-Davidson Memorial Lecture).

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. D. S. M. Watson: History of the Mammalian Ear.

SATURDAY, FEBRUARY 18.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. E. A. Gardner: Masterpieces of Greek Sculpture (1).

PHYSIOLOGICAL SOCIETY (at School of Medicine for Women, Hunter Street, W.C.1), at 4.—J. S. Haldane: Working Model to Illustrate a Theory of Muscular Contraction.—C. da Fano: Permanent Golgi-Cox Specimens.—W. W. Waller: The Microscopic Appearances of Red Blood Corpuscles in Hypertonic Saline.—W. Cramer: Slides Demonstrating the Functional Activity of the Suprarenal Medulla.—W. D. Halliburton and D. H. de Souza: Secretin by the Portal Route.—J. W. Pickering and J. A. Hewitt: Some Physico-chemical Aspects of Blood Coagulation.—J. A. Hewitt and Dorothy B. Steabben: Note on the Fermentation of Inositol. —M. Bond: (a) Fat Soluble A Content of Bacon Fat; (b) Food Value of Dried Egg-white.—E. E. Hewer: Some Observations on the Results of Suprarenal Inoculations.—M. O. P. Wiltshire: Oxygen Intake of Women during Muscular Work.—W. C. Cullis and M. Ross-Johnson: Periodic Variations in Temperature in Women.—W. C. Cullis: Oxygen Consumption as a Test of Fatigue. —G. V. Anrep and R. K. Cannan: The Blood Sugar Metabolism of the Submaxillary Gland.—A. N. Drury: The Effect of Vagal Stimulation on Intra-auricular Block produced by Cold (Mammalian Auricle).—J. Trevan and E. Boock: Note on the Effect of Section of the Vagus on the Respiratory Centre of the Cat.—H. W. Haggard and Y. Henderson: Hæmorrhage as a Form of Asphyxia.

MONDAY, FEBRUARY 20.

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting), at 7.—E. F. Hetherington and others: Discussion on The Emergency Use of Oil Fuel during the Recent Coal Strike.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—A. J. Davis: The Internal Decoration of Ocean Liners.

ARISTOTELIAN SOCIETY (at University of London Club, 21 Gower Street, W.C.1), at 8.—Prof. H. Wildon Carr, Dr. Dorothy Wrinch, Prof. T. P. Nunn, and Prof. A. N. Whitehead: Discussion on the Idealistic Interpretation of Einstein's Theory.

ROYAL SOCIETY OF ARTS, at 8.—Prof. A. F. C. Pollard: The Mechanical Design of Scientific Instruments (1) (Cantor Lecture).

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—A. F. R. Wollaston: Natural History of South-western Tibet.

TUESDAY, FEBRUARY 21.

INSTITUTION OF ELECTRICAL ENGINEERS, at 3.—Meeting in commemoration of the First Meeting of the Society of Telegraph Engineers on February 28, 1872.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Arthur Keith: Anthropological Problems of the British Empire: Racial Problems in Asia and Australasia (1).

ROYAL SOCIETY FOR THE PROTECTION OF BIRDS (at the Middlesex Guildhall, Westminster, S.W.1), at 3.—Viscount Grey of Fallodon: Address on the Work of the Society.

ROYAL STATISTICAL SOCIETY, at 5.15.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—Dr. R. Broom: The Temporal Arches of the Reptilia.—Dr. H. Blegvad: Animal Communities in the Southern North Sea.—Dr. C. F. Sonntag: (1) The Vagus and Sympathetic Nerves of the Edentata. (2) The Vagus and Sympathetic Nerves of *Hyrax capensis*.—C. Tate Regan: The Cichlid Fishes of Lake Victoria.

INSTITUTION OF CIVIL ENGINEERS, at 6.—Discussion on paper by Dr. H. F. Parshall on: Hydro-Electric Installations of the Barcelona Traction, Light and Power Company.—A. C. Walsh and W. F. Stanton: The Improvement of the Port of Valparaiso.

WOMEN'S ENGINEERING SOCIETY (at 26 George Street, W.1), at 6.15. —Mrs. H. Irving: Model Experiments in Aeronautics.

INSTITUTE OF MARINE ENGINEERS, at 6.30.—D. R. Hutchinson: Types of Large Marine Engines.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—G. A. Booth: Natural History Photography.

WEDNESDAY, FEBRUARY 22.

INSTITUTION OF ELECTRICAL ENGINEERS, at 3.30 and 8.30.—Meeting in Commemoration of the First Meeting of the Society of Telegraph Engineers on February 28, 1872.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Dr. C. W. Andrews: Description of a New Plesiosaur from the Wealden Clay of Sussex.—T. Landell-Mills, with Notes on the Petrography by Dr. A. Gilligan, and on the Palæontology by Dr. A. Smith Woodward: The Carboniferous Rocks of the Deer Lake District of Newfoundland.

ROYAL SOCIETY OF ARTS, at 8.—Dr. A. Scott: The Restoration and Preservation of Objects at the British Museum.

THURSDAY, FEBRUARY 23.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. A. G. Perkin: Dyeing: Ancient and Modern (2).

INSTITUTION OF ELECTRICAL ENGINEERS, at 3.30 and 8.—Meeting in Commemoration of the First Meeting of the Society of Telegraph Engineers on February 28, 1872.

ROYAL SOCIETY, at 4.30.—*Probable Papers*.—C. D. Ellis: β-ray Spectra and their Meaning.—Prof. A. E. Conrady: A Study of the Balance.—Dr. J. S. Owens: Suspended Impurity in the Air.—R. V. Southwell: The Free Transverse Vibrations of a Uniform

Circular Disc clamped at its Centre, and the Effects of Rotation.—A. E. Oxley: Magnetism and Atomic Structure. II. The Constitution of the Hydrogen-palladium System and other similar Systems.—T. Carleman and Prof. G. H. Hardy: Fourier's Series and Analytic Functions.—Prof. A. McAulay: Multenions and Differential Invariants. II. and III.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute, 90 Buckingham Palace Road, S.W.1), at 6.—A. E. Hayes: Phonoscript.

CONCRETE INSTITUTE, at 7.30.—H. K. Dyson: What is the Use of the Modular Ratio?

FRIDAY, FEBRUARY 24.

ASSOCIATION OF ECONOMIC BIOLOGISTS (in Botanical Lecture Theatre, Imperial College of Science and Technology), at 2.30—Dr. J. Rennie: (*a*) The Present Position of Bee Disease Research; (*b*) Demonstration of Polyhedral Disease in Tipula Species.

ROYAL SOCIETY OF ARTS (Joint Meeting of the Dominions and Colonies and Indian Sections), at 4.30.—Prof. W. A. Bone: Brown Coals and Lignites: Their Importance to the Empire.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.—Dr. H. Levy: The Number of Radio-active Transformations as Determined by Analysis of the Observations.—Prof. C. H. Lees: A Graphical Method of Treating Fresnel's Formulæ for Reflection in Transparent Media.—Research Department of the General Electric Co., Hammersmith: Demonstrations of a Sensitive Method of Determination of Density, etc.—F. C. Dyche-Teague: Demonstration of the Physical Properties of Cellactite.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—H. Main: A Pilgrimage to Provence.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—E. G. Coker: Curved Beams, Rings, and Chain Links.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. J. Joly: The Age of the Earth.

SATURDAY, FEBRUARY 25.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. E. A. Gardner: Masterpieces of Greek Sculpture (2).

PUBLIC LECTURES.

(*A number in brackets indicates the number of a lecture in a series.*)

THURSDAY, FEBRUARY 16.

INFANTS' HOSPITAL (Vincent Square, S.W.1), at 4.—Dr. W. M. Feldman: Fœtal Physiology and Fœtal Nutrition.

UNIVERSITY COLLEGE, at 5.15.—Prof. J. E. G. de Montmorency: Welsh and Irish Tribal Customs (2).

KING'S COLLEGE, at 5.30.—Dr. O. Faber: Reinforced Concrete (5).—M Beza: Nereids in Roumanian Folklore (2).

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN (Leicester Square, W.C.2), at 6.—Dr. W. K. Sibley: Seborrhœa and Psoriasis (Chesterfield Lecture).

FRIDAY, FEBRUARY 17.

METEOROLOGICAL OFFICE (South Kensington), at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (5).

KING'S COLLEGE, at 5.—Prof. R. Robinson: Orientation and Conjugation in Organic Chemistry from the Standpoint of the Theories of Partial Valency and of Latent Polarity of Atoms (2).

UNIVERSITY COLLEGE, at 5.—Prof. G. Elliot Smith: The Evolution of Man (2).

TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES (at Mary Ward Settlement, Tavistock Place, W.C.1), at 5.30.—Dr. H. Crichton Miller: The New Psychology and its Bearing on Education (4).

SATURDAY, FEBRUARY 18.

ROYAL SOCIETY OF ARTS, at 10.30 a.m.—Prof. J. A. Thomson: The Migration of Birds (Lectures for Teachers).

LONDON DAY TRAINING COLLEGE, at 11 a.m.—Prof. J. Adams: The School Class (5).

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Dr. E. Marion Delf: A Botanist in South Africa.

MONDAY, FEBRUARY 20.

UNIVERSITY COLLEGE, at 5.15.—Sir Gregory Foster: The University of London: Its History, Present Resources, and Future Possibilities (2).

CITY OF LONDON (BOYS') SCHOOL (Victoria Embankment), at 5.30.—Miss Rosa Bassett: The Dalton Plan of Self-education (3).

KING'S COLLEGE, at 5.30.—Prof. C. L. Fortescue: Wireless Transmitting Valves (5).

TUESDAY, FEBRUARY 21.

CANCER HOSPITAL (Fulham Road, S.W.3), at 4.—Sir Charles Ryall: Cancer of the Tongue.

SCHOOL OF ORIENTAL STUDIES, at 5.—Col. T. C Hodson: The Primitive Culture of India (5).

IMPERIAL COLLEGE (Royal School of Mines), at 5.30.—Col. N. T. Belaiew: The Crystallisation of Metals (1).

KING'S COLLEGE, at 5.30.—F. H. Rolt: Accurate Measurements in Mechanical Engineering: The Use and Testing of Gauges (3).

LONDON SCHOOL OF ECONOMICS AND POLITICAL SCIENCE, at 6.—Sir Josiah C. Stamp: The Administrative Factor in Government (2).

WEDNESDAY, FEBRUARY 22.

SCHOOL OF ORIENTAL STUDIES, at 12 a.m.—Miss Alice Werner: Bantu Mythology and Folklore (3). At 5.—C. O. Blagden: Matriarchy in the Malay Peninsula.

EAST LONDON COLLEGE, at 4.—Prof. F. E. Fritch: Certain Aspects of Freshwater Algal Biology (2).

LONDON (R.F.H.) SCHOOL OF MEDICINE FOR WOMEN (Hunter Street, W.C.1), at 5.—Dr. H. H. Dale: Some Recent Developments in Pharmacology (1).

HORNIMAN MUSEUM (Forest Hill), at 6.—W. W. Skeat: The Living Past in Britain (5).

UNIVERSITY COLLEGE, at 8.—The Current Work of the Biometric and Eugenics Laboratories (2).—Miss Ethel M. Elderton: The Inheritance of Intelligence.

THURSDAY, FEBRUARY 23.

INFANTS' HOSPITAL (Vincent Square, S.W.1), at 4.—Dr. W. M. Feldman: The Physiology and Pathology of the New Born; Initial Loss of Weight; Icterus Neonatorum

UNIVERSITY COLLEGE, at 5.15—Prof. J. E. G. de Montmorency: Welsh and Irish Tribal Customs (3).

KING'S COLLEGE, at 5.30.—Dr. O. Faber: Reinforced Concrete (6).

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN (Leicester Square, W.C.2), at 6.—Dr. W. Griffith: The Bullous Eruptions (Chesterfield Lecture).

BIRKBECK COLLEGE, at 8.—G. Bernard Shaw: The Failure of Education.

FRIDAY, FEBRUARY 24.

METEOROLOGICAL OFFICE (South Kensington), at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (6).

CANCER HOSPITAL (Fulham Road, S.W.3), at 4—W. E. Miles: Cancer of the Rectum.

UNIVERSITY COLLEGE, at 5.—Prof. G. Elliot Smith: The Evolution of Man (3).

TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES (at Mary Ward Settlement, Tavistock Place, W.C.1), at 5.30.—Dr. H. Crichton Miller: The New Psychology and its Bearing on Education (5).

SATURDAY, FEBRUARY 25.

LONDON DAY TRAINING COLLEGE, at 11 a.m.—Prof. J. Adams: The School·Class (6).

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Dr. W. A. Cunnington: Man's Sphere in Savage Africa.

The Function of English in Scientific Education.

THE Report of Mr. Fisher's Committee on the Teaching of English in England (pp. 394, H.M.S.O., 1921, 1*s*. 6*d*. net) has a refreshing novelty of outlook. As the serious study of English in the schools has an even shorter history than that of science, this Committee is little affected by pedagogic prejudices and vested interests, so that it is bold enough to treat all subjects taught in schools as coming within one or other of two groups, English and Science.

This classification calls for wide definitions; it is laid down that "in school, science must be, for teacher and for student, the methodical pursuit of truth and the conquest of the physical world by human intelligence and skill." The term "English" has in the past been interpreted in many ways. The public-school master of thirty or forty years ago would think of it as connoting geography, the history of England, and a little analysis and parsing, syntax and accidence. The Committee's definition is very different; it does not concern itself primarily with history or geography or with the study of language, but with the English language as a means of communication, oral and written, and with the content of books written in English as a storehouse of ideas, whether native or translated, and as an agent of emotional and æsthetic culture. Thus education is divided into "the training of the will (morals), the training of the intellect (science), and the training of the emotions (expression or creative art)," corresponding to the view that "the three main motives which actuate the human spirit are the love of goodness, the love of truth, and the love of beauty."

A separation of function of this kind has some value, if only to make us realise the necessity of each of the different components of a complete education. In practice, however, any one subject of study can and does perform several functions, overlapping those of other subjects which are akin to it. Thus some aspects of the study of English are of essential utilitarian value to a man of science, such as training in the power to write or speak clearly, lucidly, without ambiguity or prolixity, and if possible with a sense of style such that the reader may be attracted as well as instructed. But this power cannot be developed in the student without traversing much of the same ground as would be covered if the chief aim were the development of other faculties. So there will be economy of time and effort if English is used as the vehicle for an education in the humanities. It is universally agreed that, even for full efficiency in his own department, the science specialist must have such an education; it is the chief concern of the Committee to show how completely English can be made to fulfil that function.

The Committee mentions with approval the methods which have been developed at Osborne and Dartmouth in the training of naval cadets for their future career, which may be regarded as predominantly scientific, but in which they will need all the faculties of a liberally educated mind and character. For they may have to be diplomatists, tacticians, and strategists, and must certainly be leaders of men no less than practical scientific workers; they must be equipped for controlling minds as well as machines. This problem is not peculiar to the Navy, though perhaps it is more obvious there owing to the close contact, under one controlling authority, between those who train and those who employ the product of the naval college, a contact closer than is practicable, for example, between schoolmasters and leaders in the business world. Hence the experience of Dartmouth may be of more than local interest.

It says much for the prescience of the Admiralty that it should have committed itself, so far back as 1903, on the advice of the eminent man of science, Sir Alfred Ewing, who was then Director of Naval Education, to the faith that, given adequate time and skilled treatment, most of the values hitherto judged to accrue solely from a classical education were to be derived from the study of English. The experience gained during the past eighteen years in acting on this belief has gone far to justify it, and it is satisfactory to note that the methods which have been elaborated are in close

agreement, both in principle and detail, with those recommended by the present Committee.

There is little necessary connection between the study of the humanities and the teaching of languages; the latter properly falls under the head of a science, and the traditional connection arises from both having formerly been the province of one group of men. Before the days of the conflict of studies, the time devoted to Latin and Greek was far greater than was needed for the languages themselves, and the remainder was well spent on Literæ Humaniores. The present Report deals admirably with the question of the scientific and grammatical study of language; sections 254 to 266 are well worth reading in their entirety; but we are not concerned at the moment with the training of language specialists; we are, however, deeply interested in the problem of transferring to the teacher of English the functions formerly performed by the classics master in connection with the humanities. The first requisite for this transfer is to provide teachers adequately cultured; the next is to ensure the right use by them of the material available.

The Committee, therefore, had to decide what are the right methods of teaching; it also had to consider what modifications in these methods are appropriate to public elementary and preparatory schools, continuation, commercial, and technical schools, teachers' training colleges, and the universities; in addition, it felt constrained to prove that too little importance at present attaches to the study of English in all these institutions. Hence the Report covers so much ground that some search is needed to discover the teaching methods advocated.

A few extracts may, however, give some idea of the Committee's views. In commending recent progress it says:

"Exercises in both descriptive and imaginative writing, as well as practice in verse composition, in letter writing, and in dialogue, are common in the early stages. Many interesting experiments have been tried with a view to encouraging self-expression. These include debates, improvised dialogues, and dramatic scenes, and ten-minute lectures by pupils, in class as well as in out-of-school hours." "There is a far wider range of reading than formerly. . . . Rapid and enjoyable reading is no longer an exceptional thing; the class themselves take more part in the lesson and express their likes and dislikes freely." . . . "Not less important than the art of writing is the art of speaking, which includes practice not only in framing questions and answers, but also in reading aloud, recitation, debating, and drama." "A reasonable study of phonetics by the teacher should enable him to give guidance and to correct some of the most common and jarring mistakes of pronunciation." "The rendering of literature by the voice is not a mere matter of mechanical correctness, but is the final result of sympathetic entry into the spirit of the writer, and without it no education in letters can be complete."

The interest in lessons on such lines need never flag; but a note of warning is sounded. Since the reading and writing of English have an intimate and personal touch for the Englishman, they form a perfect medium for a humane education, but there is a possibility that an enthusiast may press this advantage too far and thrust himself unbidden into an inner sanctuary of the adolescent soul. It is significant that the Committee has received warning of this danger from headmasters of public schools, and not from other teachers, for a man who works in boarding-schools is apt to know more of the real boy and his reticences than the master in a day school. Hesitation on these grounds differs fundamentally from the objections of the conservative teacher whose sense of the ludicrous is stimulated by the thought of his class criticising a great author or acting scenes from a play, or of the disciplinarian who prefers the rigidity of dullness to the apparent disorder of a vividly interested class, or even of the man who feels that literature would be spoiled for the student by being read in school; but the Committee is probably right in holding that the danger is not great, and that in any event the gain is worth the danger.

In fine, to discover a medium of education in the humanities which is applicable to all sorts and conditions of Englishmen has been a vexed problem for many years, and the Committee has made an excellent case for leading us from the Abana and Pharpar of the classics to wash in the Jordan of English in order to secure a healthy and truly national system of education.

Calcium Carbide and the Board of Trade

WHAT'S A WORD WORTH?

"'THE question is,' said Alice, 'whether you *can* make words mean so many different things.'

"'The question is,' said Humpty Dumpty, 'which is to be master—that's all.'"

IT is written: "A rose by any other name would smell as sweet"; perhaps, yet there are occasions when a name may be costly to play with. One of these occurred recently, an amount running into thousands of pounds having, it is said, changed hands in the effort to disestablish the meaning of a name. Called upon to interpret the Act, christened by our Legislature the Safeguarding of Industries Act but more appropriately described as an Act for

"The Sterilisation of Scientific Inquiry, the Retardation of Industry and the Stay of Progress in Education," an Act which penalises all our scientific workers, the lawyers have been disputing over the term *Chemical* and have practically decided that it has no meaning. They have toyed with the doublet *Organic Chemical* and their dialectics have landed them in the conclusion that chemists do not in the least know where they are—so they proceed to tell them where they are not. The decisions read like those given in Wonderland, being on strictly "Humpty Dumpty" lines; they are akin to his famous reading of "*toves*":

"Well, '*toves*' are something like badgers—they're something like lizards—and they're something like corkscrews."

Now a wrangle is on over *Fine Chemical*, a term that has never been defined and is indefinable.

According to the Schedule to the Act, protection is given to "All synthetic organic chemicals . . . analytical reagents, all other fine chemicals and chemicals manufactured by fermentation processes."

The Board of Trade, putting its own interpretation upon these words, has produced a very long list of dutiable chemicals; but this is deemed so imperfect that several hundred applications have been lodged to amend it. One of the articles not on the list is Calcium Carbide and an inquiry has been held, at intervals lasting over many weeks, into the legitimacy of the claim that this substance is a synthetic organic chemical, to be ranked in the army of the protected.

An advocate learned in the law but without knowledge of chemistry, sitting unassisted by an expert assessor, after hearing many witnesses for and against, no one of whose testimony, it is obvious, could he well appraise, without attempting to deal with the adjective "synthetic," has pronounced that the carbide is not even an organic chemical.

Given such a tribunal, the issue is obviously a matter of chance; chemists would be equally unable to decide with justice in cases into which purely legal considerations entered. Still, the decision is a serious reflection upon the mental attitude of the chemist—upon his failure to think and speak only in precise terms. Unfortunately the "Ignorance of the Learned"—Hazlitt's memorable phrase—is always with us.

Calcium carbide, as every motorist and most intelligent people to-day know, gives acetylene as sole gaseous product when water is dropped upon it, the hydrogen of the water being exchanged for the calcium of the acetylide (carbide) and *vice versa*. The synthesis of acetylene, from carbon and hydrogen at the temperature of the electric arc, was first effected in 1859 by Berthelot. That the distinguished French chemist had no doubt of the organic nature of the compound is clear from the fact that he describes the method in his "Chimie Organique fondée sur la Synthèse" and also in his "Leçons sur les Méthodes générales de Synthèse en Chimie Organique" (1864). Practically speaking, it is the fundamental synthesis of organic chemistry, the foundation upon which the vast series of constructive processes which render the science so remarkable has been developed.

If there be one word in use in chemistry which, after long dispute, has a defined and accepted meaning, it is the word "organic." The dispute began with Wöhler's discovery, in 1828, that urea—the organic compound which every human being voids daily in considerable quantity—could be made by a purely artificial process: the birth of synthetic organic chemistry is to be dated from that moment; structural chemistry became possible only after Frankland had introduced the conception of valency (1852). Then system began. The prince of systematists, Kekulé, in 1851, first defined Organic Chemistry as the Chemistry of the Carbon Compounds. Others followed him. When Schorlemmer, considerably later, suggested as the better definition—The Chemistry of the Hydrocarbons and their Derivatives—he took care to point out that "compounds containing one atom of carbon such as CO_2, $COCl_2$, CS_2, HCN, which are commonly described in the inorganic part, are as much derivatives of marsh gas, CH_4, the most simple hydrocarbon, as methyl alcohol and formic acid." In his "Rise and Development of Organic Chemistry," in discussing a series of organic syntheses, he makes special reference to that of acetylene and immediately afterwards remarks: "after this the synthesis of organic compounds made rapid progress."

What does it matter where the chemist may choose to describe a carbon compound, as a matter of convenience and policy, to-day? To put port into a lower instead of into an upper bin does not change the wine to sherry. No legal dialectics can depose a substance from its proper place in the chemist's system.

In fact, the decision of the Board of Trade Referee is an offence against both chemical tradition and our chemical conscience. Appeals, with reference to chemicals, under the Act, if they are to be heard justly, should be submitted to a tribunal of chemists learned in chemical science, not to an arbitrator only learned in the law, whose attitude can but be that of "Humpty Dumpty." H. E. A.

The Pioneer of Non-Euclidean Geometry.

Girolamo Saccheri's "Euclides Vindicatus." Edited and translated by G. B. Halsted. Pp. xxx + 246. (Chicago and London: The Open Court Publishing Co., 1920.) 10*s*. net.

THIS work is an important classic, which is well worthy of inclusion in the valuable series brought out by the Open Court Publishing Co.

Sir Henry Savile, in his lectures of 1620 on Euclid I., published at Oxford in 1621, had said that in his judgment there were two blemishes (*naevi*) or blots (*labes*), and no more, in the fair body of geometry, the first being the parallel-postulate, and the second the definition of "compound ratio" in Book VI. (a definition now known to be interpolated). Saccheri's "Euclides ab omni naevo vindicatus" dealt with both *naevi* in parts 1 and 2 respectively, and from the wording of his title we may fairly infer that it was the Englishman who gave the Italian Jesuit the motive for his epoch-making treatise—that of defending Euclid and proving (if he could) that Euclid's work contained *no* flaw. The present edition is confined to part 1, on the parallel-postulate, which is alone important. Saccheri must be called the pioneer of non-Euclidean geometry, for, although it was his object to establish the truth of the Euclidean postulate once for all by showing that all hypotheses other than that of Euclid are false, he was the first to contemplate the possibility of such other hypotheses and to follow them out to a number of consequences. He is therefore, as Beltrami observed, a true precursor of Legendre and Lobachewsky, and, it might be added, of Riemann also.

Saccheri starts with a quadrilateral formed by a given straight line as base, two perpendiculars of equal length erected from the extremities of the base on the same side of it, and the straight line joining the other extremities of the equal perpendiculars. The angles made by the latter straight line with the perpendiculars respectively are easily proved to be equal. There are then, says Saccheri, three possible suppositions—the two angles may both be (1) right angles (the Euclidean hypothesis), or (2) obtuse angles, or (3) acute angles. Saccheri calls these the hypothesis of the right angle, the hypothesis of the obtuse angle, and the hypothesis of the acute angle respectively, and the object of his treatise is to prove the absolute falsity of the last two hypotheses. His proof in the case of the obtuse angle depends on the universal validity of Euclid I. 16 (which excludes the Riemann hypothesis), while his proof in the case of the acute angle is even less successful. He nevertheless proves certain important propositions afterwards proved by Legendre, Lobachewsky, and Bolyai.

Saccheri lectured on philosophy and theology, as well as mathematics, and he wrote an important logical work, the "Logica demonstrativa," brought to light by Giovanni Vailati in 1903. He was otherwise an interesting personality. We are told that he had a passion for truth, and in his pursuit of it he would (like Archimedes) neglect his person, his food, his clothes, and his comforts. As a boy of five he was a calculating prodigy. Later he became a great chess-player, being able to play (and generally to win) three games simultaneously without seeing the boards, and, as if this were not enough, to talk to people around him and also to think out some abstruse geometrical problem at the same time; afterwards he would repeat all three games from memory.

Prof. Halsted has important qualifications for editing Saccheri's treatise. He is himself an authority on non-Euclidean geometry, and has an unbounded enthusiasm for his author, which we welcome even when it leads him to write such sentences as "So flowered the beauteous body of a new geometry, mermaid-like, the latter portions somewhat fishy, but, oh! the elegant torso." It is all the more unfortunate that his execution of his task proves in many respects disappointing. The introductory matter, mainly historical, is fairly adequate, but even here there are sins of omission and commission. When he says that Father Manganotti, S.J., "accidentally discovered" Saccheri in 1889, "re-discovered" would be a better word. For Saccheri's work was thoroughly examined in Klügel's dissertation, "Conatuum praecipuorum theoriam parallelarum demonstrandi recensio" (1763), certain details about it are given in Camerer's Euclid (vol. 1, 1824), C. F. A. Jacobi mentions it (1824), and it can scarcely have been unknown to Gauss and Lobachewsky.

On pp. xviii–xix Prof. Halsted pays the editor of "The Thirteen Books of Euclid's Elements" the compliment of quoting word for word (without inverted commas) a whole page from his description of Saccheri's "Logica demonstrativa." Almost in the same breath (p. i of preface) he charges the same editor with supposing that Saccheri's "Euclides ab omni naevo vindicatus" was a "Latin edition of Euclid," a baseless charge which he need not have made if he had read the other passages of the raided work where the editor gives not only a detailed description of the book now in question, but also three long citations of proofs by Saccheri of his own propositions with diagrams, which certainly never appeared in any "edition" of Euclid. Nor is there any excuse for Prof. Halsted's omission to mention the German translation of Saccheri in Engel and Stäckel's "Die

Theorie der Parallellinien von Euklid bis Gauss" (Leipzig, 1905), a better translation, and better annotated, than his own.

To come to the translation: Prof. Halsted quotes a remark by "one of the foremost classical scholars in America" that the Latin of Saccheri is almost classical and is remarkably clear. It is a pity that it should not have been translated into equally classical English. The translation is, in fact, the reverse, and it is clear that the translator was not well equipped for this part of his task. He seems imperfectly acquainted with the force of "quin," twice mistranslating it completely; apparently he does not know the meaning of "morem gerere," since he translates "ut morem gereret tot Magnis viris . . ." by "as made a custom with so many great men . . ." (!); he renders "in rem suam" by "in his affair" instead of "for his purpose," "superetur ab" by "would exceed" instead of "would be exceeded by," "liquet" by "it flows" instead of "it is clear," "dico . . . manifestae falsitatis redargui inimicam hypothesim" by "I say I have disproved the hostile hypothesis by a manifest falsity" instead of "I say I have convicted the hostile hypothesis of manifest falsity," "ad tuendas reliquas Definitiones" by "regarding other definitions" instead of "for the purpose of maintaining other definitions." He is habitually vague as to moods and tenses, commonly translating the subjunctive by the indicative, future by present, etc. And what are we to say of such a sentence as this: "But here (*vice versa*) in fact is permitted the designation of however most small an acute angle at the point A while still the sect AB to which is to be erected the indefinite perpendicular BX, may be taken of any length whatever"? The mathematician must make of this what he can. For our part, here and in many places, we find it a relief and comfort to be able to turn for light to the Latin on the opposite page.

The Structure of East Africa.

The Rift Valleys and Geology of East Africa. By Prof. J. W. Gregory (with ten appendices by various authors). Pp. 479 + 20 plates + 5 maps. (London: Seeley, Service, and Co., Ltd., 1921.) 32s. net.

PROF. GREGORY is to be congratulated on having found, or made, opportunity to complete his work in East Africa, begun so brilliantly and adventurously in 1892–3. Returning to the country for a short visit in 1919, under favourable auspices and vastly improved conditions, he was able to collect much new information in rapid traverses, often by motor-car, where, as we are now reminded, on his previous journey his researches had been curtailed by the truculence of drunken warriors, or by drought, scarcity of game and ferocity of lions, or other such amenities of the old "safari" travel. Meanwhile there has been considerable exploration of this and neighbouring regions by other observers, and Prof. Gregory has essayed in the volume before us to combine what is known of the geology of East Africa into a coherent whole. That he has performed the task with courage and skill need scarcely be said; every scrap of information finds its appropriate place in his scheme and helps to consolidate it, so that we have a clear and logical account of the geological history of the region throughout the ages. All the rocks are classified into formations with local names and placed in position in the geological scale.

With the present meagreness of our knowledge of these vast spaces, there may seem to be a premature positiveness in the method of presentment, but the author defines his attitude explicitly in his preface: "Progress in East African geology requires a scheme by which new facts may be classified. The classification adopted is tentative and must be amended as well as amplified. Pioneer geology has to choose between the rashness of using imperfect evidence or the sterility of uncorrelated, unexplained facts." These sentences must be remembered by the reader; otherwise he may sometimes be startled at the big leap, taken with a bold "therefore," from the narrowness of the stated fact to the breadth of the deduction. Used in accordance with the author's suggestion, as an adjustable framework to accommodate new information, the book will be of particular service to every future worker in the same field, while to the geologist at large it provides the readiest means of gaining a general idea of the eastern portion of the African continent.

As implied by the title, Prof. Gregory's well-known and much-discussed conception of "the Great Rift Valley" runs as a leading theme throughout, and monopolises the shorter two of the four parts into which his book is divided. This is, however, largely a repetition, with some modification, of matter already published, here conveniently reassembled. It is parts 2 and 3, with the technical appendices, that constitute the major and most serviceable portion of the work

In part 2, consisting of twenty-two chapters, the author describes the geology, mineral resources, etc., of British East Africa (now Kenya Colony). This part contains the details of the new observations made by the author in his recent traverses; hard reading for anyone unacquainted with the ground, but invaluable to the next investigators in exhibiting the evidence on which the generalisations and classi-

I

fications are based. The recently issued first Annual Report of the Geological Department of the Uganda Protectorate prepares us for future keen discussion on several points in the proposed classifications. Some notes on prehistoric man and on caves, water supply and soils, at the end of part 2, with further information in the appendices, are of general interest. The numerous geological sketch-maps and sections in the text, though effective in a broad way, are roughly drawn and poorly printed, so that the deciphering of their detail is often troublesome. Though unavoidable, the big exaggeration of the vertical scale in all the sections, with the consequent severe distortion of the slopes, should be constantly borne in mind, since it may profoundly affect the interpretation of the structures, particularly where questions of faulting are concerned.

In part 3 our present knowledge of the stratigraphy of the neighbouring countries of East Africa and of other regions supposed to be linked up with the "Great Rift" is usefully summarised in short chapters dealing successively with Uganda and the lakes, Tanganyika Territory, Nyasaland, Madagascar, Somaliland, and Abyssinia, with some reference also to the Nile Valley and Red Sea and to the Palestine trough. A full bibliography, thirty pages in length, forming one of the appendices, adds to the value of the volume as a book of reference.

The book is embellished by some excellent reproductions of scenic photographs as plates. The diagrammatic folding-maps are adapted from those in the author's paper on African rift valleys in the *Geographical Journal* (July, 1920), and have no geological detail.

With respect to the main theme, Prof. Gregory has presented in his final chapter a lucid and concise retrospect of his opinions. He still holds that a great rift valley, stretching for more than one-sixth of the circumference of the earth, was formed by the subsidence of strips of the earth's crust between parallel tension-faults, consequent upon the breakdown of a precedent broad arch of elevation. He believes that this structure can be traced in the features of the present surface all but continuously from Palestine, by way of the Red Sea and Abyssinia, across East Central Africa, southward to the south-east coast beyond the Zambezi; with branches, eastward into the Gulf of Aden, and westward, by way of the Central Lakes, into the Upper Nile valley. The production of the "Great Rift" is assigned to movements affecting the entire earth between Upper Cretaceous and Pliocene times, and the whole story of these movements is outlined.

It may be so. Anyhow, the idea has its value as a clear-cut working hypothesis. But we really do not know much that is definite yet about the structural features on which the hypothesis rests; and as closer investigation is now in progress at many points along the supposed course of the "Rift," we may expect soon to have better grounds for judgment. Already the existence of the "Rift" along the Red Sea has been called in question by the officers of the Egyptian Geological Survey; and in Uganda the features of the "Western Rift" are pronounced by their latest investigator to be indicative of movements of compression and not of tension (*Geograph. Journ.*, November, 1921). It is generally agreed that the deep troughs of Central and East Central Africa are due to tectonic movement, with which severe faulting is associated; but it remains to be seen whether the troughs can be strung together into a continuous chain of the length and character assumed on the "Great Rift" hypothesis. Meantime let it be acknowledged that in this volume Prof. Gregory once more proves himself to be the capable champion of a bold conception which has already served, and will further serve, for fertile controversy and the increase of earth-knowledge.

G. W. L.

The Quantum Theory.

Die Quantentheorie: Ihr Ursprung und ihre Entwicklung. By Fritz Reiche. Pp. vi+231. (Berlin: Julius Springer, 1921.) 34 marks.

THIS is an admirable account of the whole field of the quantum theory, and should be very useful to anyone who has not followed it from its origin. In a subject like this, which is not yet organised into a consistent whole, it is often exceedingly difficult to judge the importance of any particular branch of the theory. One reads a paper, but cannot form an estimate of its real value, because there is not at hand all the information on cognate subjects. This is especially true of the quantum theory, for the literature is very predominantly German, and it is customary in Germany to permit the publication of much more speculative ideas than is usual in other countries, and the result is that the truth tends to get lost in the mass of paper. The great merit of the present book is that it brings together all the threads of the argument and criticises them, so that a just view can be obtained of the whole theory without struggling through a vast quantity of literature of which a good deal is of little value. It is not a mere compilation of all the views which all writers have held at all times, but a critical estimate of the opinions at present generally accepted.

The book contains 161 pages of text. The mathematics are relegated to a further seventy pages of notes, and the arrangement of these is rather tiresome, for the majority of the notes are simply references to original papers, and there is nothing in the text to distinguish between these and the mathematical calculations.

The order of treatment of subjects is mainly historical, and radiation therefore comes first. This is probably the best arrangement possible at present, though when the theory has been reduced to a classical form it is to be presumed that such a complex question will fall into a much later position. There follows a short discussion on the necessity of breaking away from ordinary mechanics, and then a description of Einstein's hypothesis of light quanta, and the ingenious deductions he makes from the fluctuations in radiant energy. The fourth chapter gives an account of the quantum theory in relation to the physics of solids—such questions as specific heats and Born's work on the dynamics of crystals. The next chapter deals with gases, where the theory is not quite so satisfactory. The rest of the book is mainly occupied with the Bohr theory. It includes all the more recent ideas, such as the correspondence principle, and also a certain amount about atom models.

There is little to criticise in such a fair account of the whole theory, but we may venture to say that the author is perhaps inclined to favour Planck's second hypothesis rather more than would the general consensus of present opinion. That hypothesis seems to give rather better agreement with experiment in the theory of gases, but neither of Planck's hypotheses has yet been made to cover the facts in a really convincing manner. On the other hand, the second hypothesis is quite foreign to the principles of spectrum theory, which agree exceedingly accurately with experiment. Apart from this, anyone wishing to get a just view of the quantum theory cannot do better than read the book.

Our Bookshelf.

Taboo and Genetics: A Study of the Biological, Sociological, and Psychological Foundation of the Family. By Dr. M. M. Knight, Dr. Iva L. Peters, and Dr. Phyllis Blanchard. Pp. xv + 255. (London: Kegan Paul and Co., Ltd.; New York: Moffat, Yard, and Co., 1921.) 10*s.* 6*d.* net.

THIS survey of the institutions connected with sexual life and the family falls into three sections. In the biological section Dr. M. M. Knight gives a lucid summary of recent work on sex, drawing the conclusion that the difference between the sexes is quantitative rather than qualitative. In the second section Dr. Iva Peters surveys the ethnological evidence for the taboo of women, and concludes that the modern form of monogamous marriage is essentially a survival of a compromise between man's erotic desires and his fears of woman's *mana*, which has produced an "ideal woman," a type out of harmony with modern developments. This is perhaps the least satisfactory of the three sections. By dwelling too exclusively on taboo and its results it ignores equally important factors in the various social complexes which influence the institution of the family. Dr. Phyllis Blanchard, in dealing with the psychological side of the question, has provided the most stimulating section of the book. By a skilful analysis she places before her readers the chief elements which are responsible for disharmony in modern marriage and the causes which, partly through the increased social activities and individualism of women, are bringing about the exclusion of a large body of the female population from participation in carrying on the race.

Sulphur and Sulphur Derivatives. By Dr. H. A. Auden. (Pitman's Common Commodities and Industries.) Pp. xviii + 101. (London: Sir Isaac Pitman and Sons, Ltd., n.d.) 3*s.* net.

DR. AUDEN gives a very readable and accurate account of the manufacture and uses of sulphur and its derivatives, especially sulphuric acid, and his book should prove useful to students and general readers. Although two illustrations of the Gill furnace are given, its mode of operation (which cannot be seen from the illustrations) is not mentioned. The changes observed on heating sulphur are not quite correctly described (p. 5). Moreover, the statement (p. 29) that "almost the whole supply of ammonium sulphate is at present derived from the distillation of coal" refers only to English practice; in more progressive countries very large quantities are produced from atmospheric nitrogen. Although the earlier history of the contact process is given, the real commercial process (p. 61) is not ascribed to any particular inventor—the work of the Badische Co. would seem worthy of mention, and diagrams of the apparatus would also be useful.

Examples in Optics. Compiled by Dr. T. J. I'A. Bromwich. Pp. 16. (Cambridge: Bowes and Bowes, 1921.) 2*s.* net.

DR. BROMWICH has collected sixty questions in optics for use in class-room at St. John's College, Cambridge, and has given references to eighty-four Tripos questions set between 1910 and 1921. The examples printed in the pamphlet cover a fairly wide range, and have evidently been selected by an experienced teacher. In many cases the questions have a direct practical application, or point towards a method of making some important optical measurement. Special attention may be directed to the examples connected with the cardinal points of a system of lenses or refracting surfaces, which should prove a useful supplement to practical work in the laboratory.

Transport of Organic Substances in Plants.

THE older writers and modern text-books affirm that the organic materials (carbohydrates, etc.) manufactured in the leaves of plants are transported downwards by means of the bast through their organs to places of consumption and storage. This belief seems to be based entirely on ringing experiments. *A priori* the bast appears to be very unsuitable for carrying out this function. Even in the most rapidly assimilating plants its cross-section is small. It is formed of short cells and comparatively short, narrow tubes, so that many cross-partitions must be traversed by the stream carrying these organic substances if they use it as a conduit. Furthermore, its resistance must be greatly increased by the fact that a large proportion of its cross-section is occupied by viscid contents—protoplasm and proteins. Evidently, in such a conduit we could only expect that velocities of transport comparable with diffusion velocities could be attained. Assuming that a 10 per cent. solution of sucrose were supplied by the leaves and that this was completely converted into an insoluble carbohydrate in a storage organ 50 cm. distant, then we might expect, after a steady state had been attained, a rate of transport, from diffusion alone, of about 2 milligrams per sq. cm. per diem. This would be equivalent to a 10 per cent. solution moving at the rate of 0·2 mm. per diem. Although this diffusion rate of transport might be somewhat accelerated by protoplasmic streaming, it is quite evident that diffusion in the bast is inadequate to account for the observed rate of transport of carbohydrates in plants. The insufficiency of diffusion to transport carbohydrates is strikingly borne out by those experiments in which cut floating leaves exposed to conditions suitable for photosynthesis accumulate carbohydrates, while only negligible quantities find their way into the water.

Close approximation to the velocity of transport in the bast, if that channel alone is used, may be obtained.

For example, a potato weighing 210 grams was attached to a stem by a slender branch about 1·6 mm. in diameter. In this branch the bast had a total cross-section of 0·422 sq. mm. This figure is a maximum, as no allowance was made for cell-walls or any non-functional element in the bast. Through this conduit, *ex hypothesi*, all the organic substance has passed during the growth of the tuber, viz. in about 100 days. According to analyses, more than 24 per cent. of the tuber is combustible; therefore we may assume that approximately 50 grams of dissolved carbohydrate has passed a conduit 0·422 sq. mm. in cross-section in 100 days. The concentration of this solution was probably not more than 10 per cent. Thus 500 c.c. of solution must have passed in 100 days, and the average rate of flow must have been 5/0·00422 cm. per diem, *i.e.* more than 1000 cm. per diem, or about 40 cm. per hour. This is evidently a much greater velocity than could be attained by diffusion in the bast, even when assisted by protoplasmic streaming.

Another way of arriving at the velocity of transport in the bast demanded by this view may be obtained from such recorded results as those of Brown and Morris on the depletion of leaves. When these results are combined with actual measurements of the total cross-section of the bast strands in the petiole we arrive at similar figures for the velocity of transport, *i.e.* if carbohydrate moves as a 10 per cent. solution the velocity of flow must be approximately 50 cm. per hour.

These considerations irresistibly force one to conclude that the cross-section of the bast is not adequate to transmit the amounts of carbohydrates actually known to travel downwards in the stems and petioles of plants. The same arguments seem to apply in ruling out the cortex as the conduit for the general transport of carbohydrates. The greater cross-section available would still be insufficient to allow the quantity transmitted by diffusion alone to account for the quantities observed.

In this connection a fact pointed out to us by Prof. Seward is of peculiar interest. In several species of tree-like Lepidodendra there is no tissue in the stem which presents the structural characteristics of bast, yet we cannot possibly assume that no transport of organic substances back from the photosynthetic organs took place in Lepidodendron.

Many observations indicate that the wood is the tissue in which this transport is effected. Hales, in 1727, published accounts of experiments showing a reversed or downward current in the stem of trees. One of us and Dr. Joly experimented with inarched branches and demonstrated a reverse current, and quite recently Ricca's brilliant work on the transport of the hormone in Mimosa renders the same phenomenon obvious (Boll. della Soc. bot. Ital., Ott., 1915, "Soluzione d'un Problema di Fisiologia," Firenze, 1916). Many observers have proved the presence of carbohydrates in the water of the tracheæ during spring, and one of us, with Dr. W. R. G. Atkins, has shown that these substances are present in a greater or less degree during the entire year (H. H. Dixon and W. R. G. Atkins, Notes from the Botanical School of Trinity College, Dublin, vol. 2, pp. 275 *et seq.*). It is only reasonable to assume that they will travel with the water current whether it moves in an upward or downward direction.[1]

Some very striking evidence for the existence of this reversed current may be obtained with plants of *Solanum tuberosum*. Thus a large potato plant was dug up from the soil with as little injury as possible to its underground stems and roots. After a short exposure to the air, but before any visible wilting had taken place, the apex of one of the leaves was cut off under a solution of eosin by means of a pair of scissors. In an hour the veins of all the leaves, the stems, and the roots were tinged with eosin. Even the roots on the far side of the tuber showed this coloration. When sections of the tuber were examined next day the strands of tracheæ in the bundles showed out with great clearness owing to their injection with eosin. This experiment was made in September.

A similar result was obtained with a specimen of *Chrysanthemum macrophyllum* left undisturbed as it grew. The tip of one of the leaves was cut off and the cut surface immersed in eosin solution at 4 p.m. on an October afternoon. Next morning the eosin was apparent in all the veins of the leaf and could be traced in the bundles of the petiole.

The transmission of clogging and poisonous substances by a reversed transpiration current has been

[1] Lately Curtis has criticised this view, basing his attack on the results of ringing experiments. He does not, however, seem to have taken into account the blocking of the tracheæ which results from morbid changes spreading inwards through the wood parenchyma and medullary rays from the injured region. These effects have been discussed at length by Strasburger, "Leitungsbahnen in den Pflanzen."

demonstrated by one of us (H. H. Dixon, Notes from the Botanical School of Trinity College, Dublin, vol. 2, pp. 5 *et seq.*) in the case of *Tilia microphylla*, *Syringa vulgaris*, *Salix viminalis*, and Philadelphus sp. Similarly, Luise Birch-Hirschfeld (*Jahrb. f. wiss. Bot.*, Bd. 59, pp. 171 *et seq.*) has shown that a solution of lithium nitrate may be carried considerable distances downwards in the reversed transpiration stream of various trees, shrubs, and herbs.

Naturally the question obtrudes itself as to how a downward current of dissolved carbohydrates is produced in the wood which is also the normal channel of the upward transpiration current. The subject calls urgently for investigation, and it may not be out of place to mention some of the hypotheses which must be tested.

If it could be shown that the wood of the vascular bundles were divided longitudinally by more or less impermeable partitions into isolated tracheal strands, we might suppose that the tension developed in the water in some of these strands by transpiring cells, while raising the sap in these, might draw down solutions ejected by adjacent cells in neighbouring strands. No such vertical partitions have been described, unless the late summer wood or the vertical plates of parenchyma in the leaf veins and petioles be regarded as such. With such longitudinal partitions a continuous and contemporaneous upward and downward transport might be developed.

An intermittent downward flow might be explained if we could obtain evidence of a periodic or occasional development of permeability in the protoplasmic utricle of the transpiring cells. This might be developed in response to any stimulus, *e.g.* the mounting of tension in the adjacent sap above a certain limit.

The periodic mounting of tension with consequent contraction of the stem, which is indicated in the experiment on the potato plant quoted above, has been established by the elegant observations of Mallock (Proc. Roy. Soc., 1919, vol. 90, B, pp. 186–91) and of MacDougal ("Growth in Trees," Carnegie Institution of Washington, Washington, 1921). These latter show graphically the change of volume of the woody stem of forest trees corresponding to the diurnal period.

Again, the deposit of dew on the transpiring cells, in conjunction with a high tension, might determine a downward flow in the tracheæ, and, with suitable modification of the permeability of these cells, this downward stream might be charged with dissolved carbohydrates.

It is quite evident that the tension assumed here may be developed by temperature changes of the water in the woody tissues and by recovery from flexure just as well as by evaporation. That tension is really responsible is indicated by the experiments quoted above, and also by the fact that no transport occurs from cut leaves floating in water.

If the view that the longitudinal transport of organic substances takes place in the tracheæ is established, speculation naturally arises as to the function of the bast. While the form and arrangement of this tissue seem to preclude any important longitudinal transmission within it, its large peripheral surface and the area of its contact with the cambium and medullary rays seem to suit it for the transmission of organic substances in a radial direction. In this connection the medullary rays may have the function of discharging into, and extracting from, the tracheæ organic substances which are transmitted to and from them by the bast. The observations made by Atkins and one of us that the concentration of carbohydrates in the conducting tracts often diminishes from below upwards suggests that these substances may be extracted from the transpiration current in its upward movement (H. H. Dixon and W. R. G. Atkins, Notes from the Botanical School of Trinity College, Dublin, vol. 2, pp. 335 *et seq.*). The presence of starch in the medullary-ray cells in many plants at all times of the year suggests that the carbohydrates are fixed in these cells as starch. Solution by enzymes of this starch in response to an upward or a downward movement of the water in the tracheæ would provide a mechanism for the upward or downward transport of these substances in the transpiration stream.

It is hoped by experiments which are now in progress to throw some further light on this fundamental problem of plant physiology.

Lunar Periodicity in Reproduction.

It is a common belief in many fish-markets around the Mediterranean and in other parts of the world that the amount of edible matter in sea-urchins and certain other invertebrates varies with the phases of the moon. The animals are said to be "full" when the moon is full and "empty" at new moon. This belief was recorded by Aristotle, Pliny, and other classical writers, and was stated by them to apply not only to sea-urchins, but also to oysters and other molluscs.

During the summers of 1920 and 1921 I made systematic examinations of the gonads of an Echinoid (*Diadema setasum*) at Suez with the object of testing the truth of the popular statement. I found the latter to be founded on fact to a surprising degree. There is a periodic reproductive cycle in this species of Echinoid which is correlated with the lunar period, the genital products being discharged into the sea at about each full moon during the breeding season. An examination of the testes and ovaries of a number of individuals between the first quarter and full moon shows the majority to be swollen and full of mature spermatozoa or eggs, while a lesser number are "spent," *i.e.* show evidence of having lately extruded their genital products. A week later the relative proportions are reversed. Some individuals have gonads still full of spermatozoa or eggs, but most are now "spent." Between the third quarter and the new moon all gonads are shrunken in size and contain nothing but developing spermatocytes or oocytes. From now onwards until the first quarter of the next moon these cells show progressive stages in development into spermatozoa and eggs which are to be spawned at about the time of full moon. This lunar cycle is repeated throughout the breeding season.

In seeking a causal connection between the reproductive rhythm and the lunar month an influence of the tides first suggests itself. But whereas there is a single reproductive cycle in each lunation, there are two spring and neap tidal periods, *i.e.* a double cycle. However, during the summer months at Suez the new moon spring tides have a greater range than those of the full moon, so that the maximum tidal range is attained only once during each lunar month. The higher and lower water at the new moon spring tides might conceivably react on the Echinoids by the different hydrostatic pressure (affecting, *e.g.*, the tension of dissolved gases) or by causing the animals to be at a greater or less distance than usual from the source of oxygen or of light. But the average excess tidal range at new moon spring tides over that at full moon spring tides during the period studied was only 58 cm. This small difference could scarcely affect the

urchins, for they are not sessile animals, but move actively, their vertical range of migration during the course of an hour being far in excess of this figure.

The possibility of tidal influence could be tested by keeping urchins in a floating cage. If the lunar reproductive cycle were thereby abolished, the tidal connection would be demonstrated; a contrary result from the experiment, however, would not dispose of a possible influence of the tides, for an established rhythm in a physiological process is often persistent after the original cause has been removed. Unfortunately the experiment was impracticable with Diadema owing to its size. Full-grown specimens measure more than one foot from tip to tip of the spines, and it was impossible to obtain large enough floating boxes to contain a hundred or more individuals. I intend, however, to seek further evidence regarding the possible effect of tides by studying Echinoids in localities with greater and smaller tidal ranges than at Suez. I am convinced, though, that if a similar lunar reproductive cycle exists in the sea-urchins at Naples or at Plymouth it is very little pronounced; for I have made use of the Echinoids at these places to obtain spermatozoa and ova for other experimental purposes for months on end without ever noticing a rhythmic variation in the condition or quantity of the genital products. At Suez the period in each lunar month when spermatozoa and eggs are unobtainable would necessarily force itself upon the notice of the investigator.

The possibility of a direct effect of the light of the moon on the Echinoids could be tested by keeping specimens in the dark. Although the large size of Diadema again precluded this experiment at Suez, I intend to carry it out in another place with a smaller Echinoid. If the light has an effect it must necessarily be more constant in the cloudless summer nights of Egypt than in Europe. It was thought possible that the light of the moon might act by causing the urchins to feed either more or less than usual on moonlit nights. A systematic examination of gut contents showed that this was not the case.

Other marine animals popularly believed in Egypt to vary with the moon are mussels and crabs. Contrary to the case of the sea-urchins, I have found these beliefs to be without foundation.

Now it is obvious that the periodic spawning of Diadema must be reflected in the plankton of the Gulf of Suez. The plutei must vary in quantity and in stage of development with the phases of the moon. By an examination of plankton from different parts of the world I hope to discover which of the animals having pelagic larvæ show a lunar reproductive cycle.

The best known example of lunar reproductive periodicity at the present time is the Palolo worm. In the South Pacific these Polychætes swarm at the surface of the sea to discharge their genital products at the third quarter of the October and November moon (Friedländer, *Biol. Centralbl.*, 1898–1901). In Japan another Palolo swarms at both full and new moon, *i.e.* at the spring tides (Izuka, Journ. Coll. Sci. Tokyo, 1903), while in the Atlantic a third species has similar habits (Mayer, Carnegie Inst. Pubs., 1909). Odontosyllis in Bermuda (Galloway and Welch, Tr. Am. Micr. Soc., 1911) and British Columbia (Potts, Proc. Camb. Phil. Soc., 1913), and Nereis (Lillie and Just, Biol. Bull., 1913) and Platynereis (Just, Biol. Bull., 1914) at Woods Hole, Massachusetts, have been shown to swarm at one definite phase of the moon, whereas Nereis at Naples (Hempelmann, *Zoologica*, 1911) swarms at about the first and third quarters. The latter bi-lunar, *i.e.* apparently tidal, periodicity is remarkable, since the tidal range at Naples is much smaller than at Woods Hole. Another Polychæte, Amphitrite, lays its eggs at new and full moon spring tides at Woods Hole (Scott, Biol. Bull., 1909), as does also the Turbellarian Convoluta in Brittany (Gamble and Keeble, Quart. Journ. Micr. Soc., 1903).

To my knowledge the only other case of reproductive periodicity in animals correlated with the lunar period is in the human race. Arrhenius (Skand. Arch. f. Physiol., 1898) showed statistically that there exists a low correlation between the menstrual period and the (tropical) lunar month. In addition, he found traces of a consequent tropical lunar periodicity in birth frequency.

The only authentic cases of lunar rhythm in the reproduction of plants seem to be among the algæ. In North Carolina Dictyota produces one crop of sexual products in each lunar month (Hoyt, *Bot. Gaz.*, 1907). The same plant at Naples (Lewis, *Bot. Gaz.*, 1910), and at Plymouth and Bangor (Williams, *Ann. Bot.*, 1905), has a tidal reproductive rhythm, *i.e.* two cycles per lunation, as is also the case with Sargassum (Tahara, *Bot. Mag.*, Tokyo, 1909).

Popular beliefs in the influence of the moon on plant growth are world-wide, although most of them are probably on a par with the superstition that a waxing moon increases and a waning moon decreases any process, such as the acquisition of wealth, the growth of corns, nails, hair, etc. In Egypt it is said that melons and other fruits of the Cucurbitaceæ grow most rapidly on moonlit nights. The belief that sowing and planting must be done in a waxing, and reaping and cutting in a waning, moon is very widespread. As regards cutting, experiments made recently in Trinidad by Rorer have proved the superstition to be without foundation. It is conceivable, nevertheless, that moonlight may have a photosynthetic effect. Kofoid (Bull. Ill. State Lab. of Nat. Hist., 1903 and 1908) and Allen (Univ. Cal. Pubs. Zool., 1920) have found a maximum frequency of plankton algæ in certain North American rivers occurring at full moon. Kofoid attributes this to lunar photosynthesis, quoting experiments of Knaute (*Biol. Centralbl.*, 1898) in support of his hypothesis. Owing to the great importance of this possibility, and since Knaute obtained a surprisingly large amount of photosynthesis in moonlight, I am at present repeating his work.

I should be grateful if readers of Nature would communicate to me popular beliefs in lunar influence on animals or plants. It is possible that some of them may prove upon investigation to be as well founded on fact as the case of Diadema.

School of Medicine, Cairo, January 25.

Research Degrees and the University of London.

There are at present four degrees in the faculty of science of the University of London which may be granted for a research thesis, namely, D.Sc., Ph.D., M.Sc., and (in exceptional cases only) B.Sc. If a recent report by a sub-committee of the Academic Council should be finally adopted by the University, these four will be reduced to two, D.Sc. and Ph.D., while a new series of examinations will be introduced for M.Sc. As I feel very strongly (with many of my geological colleagues) that this would be a mistaken policy, I venture to ask for space in the columns of Nature to state my reasons for that feeling.

It would scarcely be necessary to refer to the case of B.Sc. by research but for the serious misconceptions on the subject shown in the sub-committee's report. The granting of this degree is a very rare event, and I have no personal knowledge of any case

of its being granted, but I have always understood that it was reserved for the exceptional case of a serious scientific investigator whose academic career has been interrupted after the intermediate stage and who wishes to resume it at an age when the concentrated study necessary for the passing of the final B.Sc. examination cannot reasonably be required of him. If there is any reason to fear possible abuse of this means of graduating, it would be a simple matter to fix a minimum age-limit for it—say thirty-five—rather than to abolish it.

The immediate importance of the B.Sc. by research, however, is that it gives the sub-committee an opportunity to exaggerate the number of standards of research which examiners have to keep in their minds. The report says: "We do not consider it satisfactory that there should be as many as three, and still less four, degree standards of research." There is no fourth standard. I cannot conceive any examiner recommending the B.Sc. degree for a thesis which would be rejected for M.Sc. if offered by a graduate. On the contrary, I can easily imagine the University making it a rule to accept no thesis for B.Sc. which it would not accept for Ph.D., or even D.Sc., if this means of graduation is reserved for very exceptional cases. The conditions under which alone B.Sc. by research should be granted forbid the standard from making a fourth with the three standards of post-graduate research degrees. As to those three standards, as an examiner I have not found any difficulty in framing three standards in my own mind or in agreeing upon them with my colleagues. On the contrary, I find that the introduction of the Ph.D. degree has made it easier to define the standards of the two others. If the M.Sc. by research be abolished, the Ph.D. standard will inevitably tend to sink, until in a few years it will be equivalent to the present M.Sc.

I am certainly not speaking for myself alone when I express myself as strongly in favour of the retention of the M.Sc. by research; but if the University should decide to abolish it, I should very much prefer the abolition to be complete rather than that the degree should be granted by examination. The work of a candidate for M.Sc. by research must necessarily consist very largely (in some cases entirely) in a survey of the knowledge already acquired on the subject which he proposes to investigate. This involves the intensive study of original works of research possibly going far back into the early history of science and extending into various branches, all connected together by their bearing on some one problem. In geology, for instance, such an investigation may often include portions of the several branches—petrology, stratigraphy, palæontology, and economic geology.

A candidate studying for M.Sc. by examination will be engaged on very similar work, but its boundaries will be arbitrarily determined for him by the definition of some particular subject which he chooses from a published list. He will be warned off side-issues that may attract him by the fact that they will not form part of the subject-matter of his examination. He will be much more inclined to rely on text-books than on original papers, and any tendency to run down obscure questions for himself in the literature of the subject or by personal observation and research will be positively disadvantageous to him, since he will be discovering facts probably unknown to his examiners.

Examples could easily be found of able investigators whose life-work originated as a side-issue from an early line of study. At the beginning of post-graduate life a man cannot be expected to choose irrevocably his main line of work.

As an examiner I am convinced that the Honours B.Sc. stage is the highest at which examinations are of value, except as an altogether subordinate part of the qualifying test. After this stage every incentive should be given to the student to work on lines determined by his particular interests and opportunities, and not by what must be, even when every effort is made to avoid it, an arbitrary pigeon-hole sub-division of the sciences. A. MORLEY DAVIES.

Imperial College, S.W.7, February 9.

The Accuracy of Tide-predicting Machines.

I SHOULD like to make a few comments on Mr. Marmer's letter in NATURE of February 2, p. 136, as I was responsible for the tests made on the British machines referred to in your review of "British Research Work on Tides."

In his last paragraph Mr. Marmer states the various uses that can be made of tide-predicting machines in addition to their normal use. Most of these are quite likely to be well within the capacity of any machine, since relatively small quantities only are involved and the full scale of the machine can be used. But their use in "the elimination from the observed tide of the tide due to a number of constituents" is precisely that which was shown to be undesirable so far as the British machines were concerned. It has been found very advantageous in research work to subtract known constituents from the tidal record and to examine the residue, but for such work it is of prime importance to know that what we have actually removed is exactly what it professes to be. It is not desirable to spend time and energy on the examination of fictitious residues due to machine errors, and it was found that the British machines were subject to systematic errors of about 0·5 ft. in hourly heights (though not in heights of high and low water), with a spring range of 18 ft. Such errors entirely prohibited the use of these machines.

It is quite probable that the performance of the British machines can be improved, but the labour of reading the curves will be great. In this respect the U.S.A. machine has a notable advantage, and I should be very glad to know that one could obtain from it hourly heights with an accuracy suitable for research work, say to within 0·05 ft. for a spring range of 30 ft. But in fairness to the British machines, and not with a desire to impeach the working of the U.S.A. machine, I must say that I am not convinced by the tests recorded by Mr. Marmer. At Hong Kong the spring range of tide is only 4·5 ft., and if the full powers of the machine have been used, as is reasonable to suppose, then we should expect a *pro rata* error of 0·4 ft. with a spring range of 30 ft. It is fervently to be hoped that such is not the case, though I must confess that certain comparisons I have made between direct calculations and U.S.A. predictions show discrepancies of this magnitude, even in high- and low-water heights. Further, the difference in predictions between the U.S.A. machine and one of the British machines is much greater than is to be expected, if it be due to the errors only of the latter.

It is very noteworthy that the performance of the U.S.A. machine in 1922 agrees very well with its performance in 1910, indicating that its errors are truly systematic; but this is no consolation to a research worker unless he knows what the errors are. It is easy to see that the errors have not any obvious relationship to the actual tide predicted. The tests illustrate the difficulty one would have in dealing with the residues, for of the thirty constituents used about half are individually less than the error of the machine.

If only the largest constituents had been used the task of analysing for the remainder would have been made more onerous by the presence of this error, and much more so if there were unknown constituents to deal with.

I quite agree with Mr. Marmer that the only satisfactory method of testing the machines is to compare their results with the results of numerical or "hand" calculations, but such tests should be exhaustive and convincing. A. T. DOODSON.

The Brittleness of Ice at Low Temperatures.

SIR GEORGE BEILBY ("Aggregation and Flow of Solids," 1921) has recently directed attention to the impossibility of explaining the flow of glaciers at temperatures much below 0° C. on the regelation hypothesis, and the necessity for assuming a deformation of the ice-crystals by displacement along internal-glide planes or at the crystal boundaries. From his experiments on the behaviour of metals and minerals under pressure he suggests that in ice a vitreous modification will be produced at the plane of displacement, and that above a certain temperature—the "crystallisation temperature"—this will immediately revert to the crystalline state, the process being repeated indefinitely during movement. Should the temperature of the ice fall below this point it is predicted that the flow will be retarded, as the vitreous modifications of metals are harder than the crystalline, and their presence promotes rigidity.

It seems that here we have an explanation of the brittleness of ice at low temperatures. Navigators in the pack have noticed that the development of the pressure ridges is noiseless in summer, but accompanied by loud detonations in winter. Another consequence of the existence of this state at low temperatures is well known to every ski-runner in a distinct loss of gliding power. Sir George Beilby has shown that the "crystallisation temperature" for ice must lie somewhere below −12° C. There is general agreement in Norway that the "føre," though deteriorating slowly as the temperature falls below −5° C., receives a marked check at about −17° C., and Nansen's observations in the pack are fairly consistent with this figure. To test the validity of the explanation offered we must await the experimental determination of the "crystallisation temperature" of ice. L. HAWKES.

Age Incidence of Influenza.

WAS not the unusual age incidence of deaths in the influenza epidemic of 1918–19, referred to in NATURE of February 2, p. 130, due to the special circumstances of that time? With few exceptions, all civilians in this country at that date between the ages of twenty and thirty-five could have been placed in one of three classes:—

(1) Persons engaged in war-work on the land, in factories, offices, etc. All these were doing a full man's working day (judged by the standard of normal times), and many were seriously overworking.

(2) Ex-Service men discharged on account of ill-health.

(3) Mothers of young children, who in many cases went short of food themselves in order to ensure an increased ration for their families.

None of these would have been so resistant to infection, or so well able to throw off disease when contracted, as they would have been in normal times. ANNIE D. BETTS.

MISS BETTS suggests that the exceptional incidence of influenza mortality during the pandemic of 1918–19 may have been caused by the exceptional war-conditions, leading to the greatly increased occupation of women, to overwork of these and of men, and to the state of health of ex-Service men. To these suggested causes may be added the effect of the rationing of food, which might affect to an exceptional extent the mothers of young children.

These explanations of the strangely inverted age incidence of influenza mortality have been often debated. They cannot explain the course of events more than to a minor extent. For (1) with such an infectious disease as influenza domestic infection of older persons, even when they had escaped extra-domestic infection, must have been the general rule. War-conditions must surely have told heavily on aged persons.

(2) Curves given on p. 41 of the Registrar-General's Report on Influenza (Cmd. 700) show that this change in age incidence was unparalleled in the history of the disease, and that the changed age incidence characterised the beginning of each of the three consecutive waves of the disease. With the progress of each there was a diminishing youthfulness of decedents.

(3) This change in age incidence was not confined to this country or to other belligerent countries especially affected by war-conditions. It occurred, for instance, in Scandinavian countries and in America.

(4) The explanation that those attacked in the 1889–91 epidemic—the older section of the population—were relatively immune is not supported by any adequate body of evidence.

In short, the altered age incidence of influenza in the recent epidemic remains an unsolved problem. An easy way out of the difficulty, though a way probably not according with facts, would be to assert that the recent pandemic was a different disease from that of 1889–92. THE WRITER OF THE ARTICLE.

Dr. Frank Bottomley.

MAY I be permitted to make a correction of an error in Sir Richard Paget's obituary notice of my cousin, Dr. Frank Bottomley, in NATURE of February 16, p. 212? Sir Richard states that Frank Bottomley's stepmother was "the widowed sister of Lord Kelvin." Frank Bottomley's father, being a son of Lord Kelvin's sister Anna, could not possibly have married another of the sisters. Lord Kelvin had three sisters, namely, Elizabeth, widow of the Rev. David King (she never remarried); Anna, Mrs. William Bottomley, who was Frank Bottomley's grandmother; and Margaret, who died in early childhood. As a matter of fact, Frank Bottomley's stepmother was a sister of Lord Kelvin's second wife.

Thermo-electric Instrument for Measuring Radiation from the Sky.

IN the note on Mr. W. H. Dines's memoir on "Observations of Radiation from the Sky" (NATURE, January 12, p. 54) you attribute to me the final design of the instrument. Permit me to say that Mr. Dines greatly elaborated and improved the thermo-electric instrument after I left it.

The Mechanism of Heredity.

By PROF. T. H. MORGAN, Columbia University, New York City, U.S.A.

I.

Mendel's Two Laws of Heredity and their Mechanism.

AT the time when Mendel discovered his two fundamental laws of heredity, no mechanism was known in plants or animals that would explain how such processes as those invoked by him could be brought about; but between 1865 and 1900 (when Mendel's "Principles" were recovered), the study of the ripening process (maturation) of the egg and sperm-cell had progressed so far that such a mechanism was ready at hand.

Mendel's first law—the law of segregation—may be illustrated by the following example: A tall edible pea crossed to a short pea gives tall (hybrid) offspring. These, if self-fertilised, produce on an average three talls to one short. Mendel pointed out that a very simple hypothesis will account for this ratio of 3 : 1 in the second generation (F_2). The original tall parent contributes one element (T), and the short parent another element (*t*) to the hybrid. If at the time when its germ-cells mature these elements separate (segregate), so that half the eggs come to contain the element for tallness (T), and the other half the element for shortness (*t*), and if a similar process takes place in the pollen of the hybrid (half the pollen grains bearing T and half *t*), then chance fertilisation of any egg by any pollen grain will be expected to give three kinds of individuals, namely TT, T*t*, *tt*, in the ratio of 1 : 2 : 1. The first two kinds (TT and T*t*) will be tall plants, because the one (TT) is pure for tallness, and because in the other (T*t*) tallness dominates shortness as seen in the hybrid. Hence the second generation will be made up of three talls to one short.

The unique feature of the situation, the segregation in the germ-cells of the hybrid of the elements derived from each parent, finds a parallel in the distribution of the maternal and paternal chromosomes of the hybrid. For example: every cell of the hybrid contains one chromosome (*a*) from one parent, and one chromosome (A, the mate of the former) from the other parent. But this condition is not permanent in its germ-cells, for when they arrive at the final ripening stage, the two chromosomes (*a*A) come together, conjugate, and then "segregate," *i.e.* they pass into opposite cells. As a result, half the eggs contain chromosome *a*, half chromosome A. They behave like Mendel's pair of "characters." Hence if the materials responsible for the difference between T and *t* are carried by the members of the same pair of chromosomes, A and *a*, they must follow Mendel's first law.

Mendel's second law applies to the independent behaviour of two or more pairs of characters: the members of each pair assorting independently of the members of other pairs. It has been generally supposed by cytologists that at the ripening of the germ-cells the members of the pairs of chromosomes separate independently, in the same way that Mendel supposed the individual pairs of characters to be distributed. Proof was difficult to obtain from direct observation, but recently this evidence has been abundantly and convincingly obtained by Miss Carothers. If then the chromosomes carry the materials (genes or differentials) for the hereditary characters, they behave in such a way as to ensure the success of Mendel's second law.

Had we only this parallelism to go upon we should be justified, I think, in accepting the chromosome theory of heredity as a working hypothesis, but further evidence has been steadily accumulating. It may be briefly summarised, yet

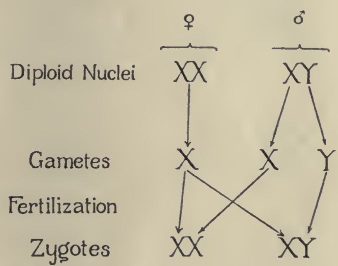

FIG. 1.

must be given in some detail; for it is the exact correspondence between fact and theory that furnishes the essential data for the conclusions arrived at.

(1) In some groups of animals it has been shown that one pair of chromosomes (XY) acts as a differential with respect to sex determination (Fig. 1). The female has two like chromosomes, called X and X; the male has one X, and often another chromosome called Y. Thus XX = ♀; XY = ♂. These chromosomes segregate at maturation, as do the others. Every egg eliminates one X in one of its polar bodies; half the sperms are X-bearing, half Y-bearing. Any egg (X) fertilised by an X-sperm = XX (♀); any egg (X) fertilised by a Y-sperm = XY (♂). Thus sex is here determined by a process that automatically gives equal numbers of males and females.

A son always gets his single X from his mother; a daughter gets one X from her mother, another from her father. Certain characters follow in their heredity the course taken by these chromosomes. For instance, if the mother is *aa*, and the father is A, each son will be *a*, each daughter will be *a*A.

Many examples of this sort could be given, and further tests of the different kinds of individuals that appear in such crosses could also be cited to show that the distribution of the sex-linked characters follows the distribution of the X-chromosomes. This evidence is so significant that it may be further illustrated by a concrete case. If a white-eyed female of the vinegar fly, *Drosophila melanogaster,* is bred to a red-eyed male (Fig. 2), the sons are white-eyed, and the daughters are red-eyed (red dominates white). If these are inbred there appear in the next generation white-eyed daughters, red-eyed daughters, white-eyed sons, and red-eyed sons in the ratio of 1 : 1 : 1 : 1.

The distribution of the X- and Y-chromosomes is illustrated by the rods in the middle of the diagram. The white rod stands for the X that carries the differential for recessive white eyes. The black rod stands for the X that carries the

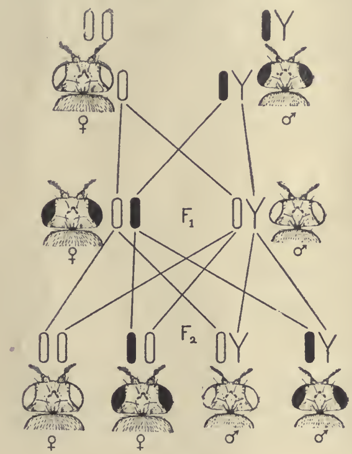

FIG. 2.

differential for dominant red eyes. The Y-chromosome is represented by that letter. It is obvious from the way in which these chromosomes are distributed that there should be both red-eyed and white-eyed grandchildren in equal numbers.

The reciprocal cross gives a different result (Fig. 3). Thus, when a white-eyed male is bred to a red-eyed female, both the sons and the daughters have red eyes. If these are inbred, there appear in the next generation red-eyed daughters, red-eyed sons, and white-eyed sons in the ratio of 2 : 1 : 1. Here also it is evident from the distribution of the X's why, in the second generation, the only white-eyed flies present are males. These carry a single white-producing X that traces back to the grandfather. All the granddaughters have red eyes, but are of two kinds, one pure for red, and the other carries both a red and a white rod. If these second-generation females are tested it is found, in fact, that half of them carry two red-producing chromosomes, and the other half a red and a white one. Evidence like this from sex-linked inheritance, where both the genetic and the chromosomal histories are known, furnishes by itself very strong evidence in favour of the chromosomal interpretation of heredity, but there is further evidence that makes the case even stronger. This evidence may now be briefly stated.

(2) Individual females of the fly Drosophila are

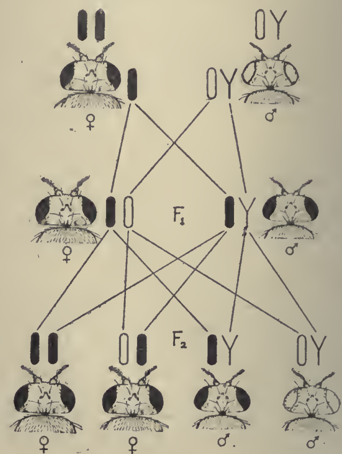

FIG. 3.

sometimes met with that break the rule for sex-linked inheritance. A genetic study by Bridges of this exceptional behaviour led to the prediction that they must have an extra sex-chromosome. Cytological examination showed, in fact, that there is in these females an X- and another X- and a Y-chromosome (Fig. 4). The genetic behaviour of the "non-disjunctional" females is so important for the chromosome theory that it must be followed through carefully. It will be simpler to give the genetic and the chromosome histories together.

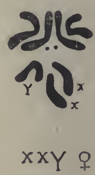

FIG. 4.

When an egg containing the three chromosomes XXY matures, the two X's may conjugate, leaving the Y free to go to either pole of the polar spindle (this happens in 92 per cent. of the cases), or else an X and the Y may conjugate, leaving the other X to go to either pole. As shown in the diagram (Fig. 5), four kinds of eggs result (and four kinds of polar bodies are extruded). If the non-disjunctional female in question has white eyes, the history of her white-bearing X's can be followed when she is fertilised by a male with a red-bearing X-chromosome. Considering first the fertilisation of her four kinds of eggs by the red-producing X-sperm of the male, it is evident that there will be produced four kinds of individuals, viz. XXY, XX, XXX, and XY.

Two of these red-eyed females are both hybrid for white; one of them should be a non-disjunctional female (XXY) and repeat the same process. Such

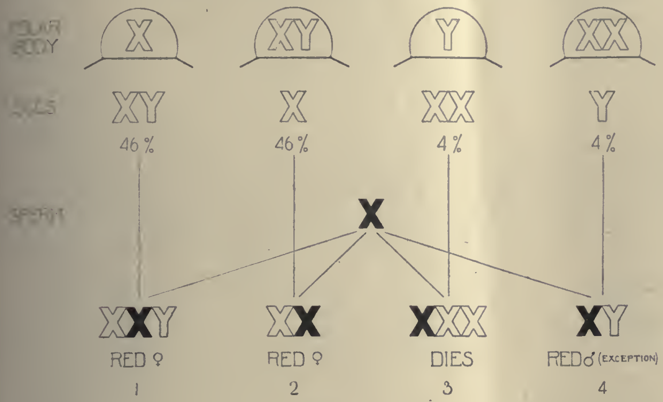

FIG. 5.

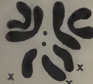
is the case. The females with three X's generally die, but occasionally one emerges that can be identified as such by certain peculiarities, and when the cells of such a female are studied it is found that three X's are present (Fig. 6). Lastly, there is a male, XY, with red eyes, an "exceptional male," since his mother had white eyes. He arises from a Y-egg fertilised by an X-bearing sperm—the so-called female-producing sperm. Here such a sperm makes a male because the combination of one X with the rest of the chromosomes is a male in these flies, quite irrespective of the origin of the X-chromosome. The result shows convincingly that the X-sperm normally gives rise to a female because it carries an X (the egg supplying another X), and not because its X is carried by a "female-producing" sperm.



XXX ♀

FIG. 6.

There remains to be considered the case where the same series of eggs is fertilised by the other kind of sperm, the Y-bearing sperm. In the lower line of Fig. 7 the outcome is shown. Two kinds of males appear, both white-eyed, but one XYY and the other XY. The latter, XY, is found to be a normal male; the former is expected, in some cases, to transmit both an X and a Y through his "female-producing" sperm and give rise in this way to non-disjunctional daughters (XXY). This, in fact, has been shown to occur.

The single class of females that appears in this series arises from the fertilisation of the XX-egg by a "male-producing" (Y) sperm. She has white eyes and "breaks the rule." She must, furthermore, from her origin, be herself a non-disjunctional female, and, in fact, has been shown to behave as such. Finally, the YY individual in the diagram is not found, and probably dies, as is to be expected, since it contains no X-chromosomes.

(3) From an entirely different source new proof of the chromosome theory has been found. This, too, involves the sex-chromosomes. We have a stock that gives results diametrically opposite to ordinary sex-linked inheritance. The females

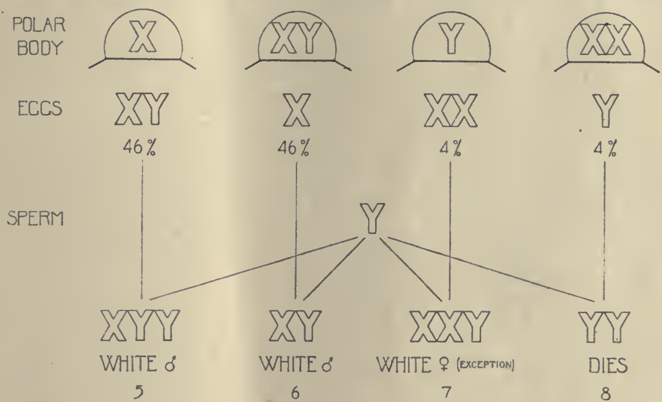


FIG. 7.

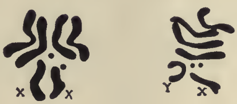
are yellow (recessive), and give, when bred to a normal grey male, yellow daughters and grey sons. A study of this stock by L. V. Morgan, who discovered it, showed that all the results could be explained by the assumption that two X-chromosomes, bearing yellow, had become stuck together. Sections of these females verified the prediction. Two united X-chromosomes and a Y are present in the yellow females (Fig. 8). At maturation of the eggs both X's pass out together into the polar body at the reduction division, or else both remain in the egg. Thus the mature eggs are XX or Y. Fertilised by a normal "grey" X-sperm, the XX egg gives an XXX grey female (which dies as a rule) and an XY

grey male. Fertilised by a Y-sperm, the two kinds of eggs give XXY yellow females and YY individuals (which die). Thus, of the four kinds of individuals expected, half the females (XXX) and half the males (YY) die, and a sex ratio of 1 : 1 remains. It has been stated above that XXX females appear at rare intervals. These are grey and are recognisable as XXX individuals by certain stigmata, and have been shown in sections to possess the three X's.

(4) Drosophila, and presumably other animals belonging to the XX–XY type, are so constituted that they can develop with one X or with two X's, provided the other chromosomes are present in duplex. In short, sex determination has been

FIG. 8.

regulated along these lines. Failure to obtain similar situations in the case of the other chromosomes led us to suppose that an individual lacking one or both members of a pair could not "come through"; but we had no actual proof that this was the explanation of their absence. Nevertheless, it was anticipated that it might be possible for individuals lacking one or containing three of the very tiny IV-chromosomes (Fig. 9) to survive. Recently Bridges has found such individuals, and we now realise that they must have been rather frequently met with in the past, but were not recognised as such. A fly with only one of the IV-chromosomes is small, pale, hatches late, has small, slender bristles and a dark trident. The



XX ♀ XY ♂

FIG. 9.

wings are blunt and slightly spread, and the eyes large and roundish. If a female, it is expected to contain two kinds of mature eggs (*i.e.* eggs after the polar body has been extruded)—one kind with, the other kind without, a IV-chromosome. The egg with one IV-chromosome gives a normal result when fertilised. The egg without a IV-chromosome, if fertilised by a sperm carrying a recessive IV-chromosome character, produces an individual (♂ or ♀) showing the recessive character of the father, because the single IV-chromosome of this individual came from the father that carried the recessive in question. A male that has only one IV-chromosome in its cells produces two kinds of sperm, one with IV and one without IV. Mated to a normal female, the results are in principle the same as above. A male and a female, each with only one IV-chromosome, when mated, might be expected to give some individuals (25 per cent.) without a IV. None such appear, and the ratios show that they die.

Individuals with three IV's are also known. Their characteristics are the opposites of those shown by the haplo-IV's. For example, they are dark with a very faint trident, long-bristled, and have small, smooth eyes. Their wings are long and narrow. Females of this kind produce two kinds of eggs, one kind with two IV's, the other kind with one IV. Mated to a normal male, with a IV-chromosome recessive character, such females produce daughters and sons of two kinds, namely, one kind with three IV's, like the mother, and the other kind normal.

If these males and females, triploid for IV, are mated, the recessive character appears in only 4 per cent. instead of the Mendelian 25 per cent. of the offspring, as would be expected when one recessive and two dominant characters are involved.

Many combinations between triploids and haploids are possible, and unique ratios are expected. These have also been worked out. Cytological preparations of triplo- and haplo-IV's show in

FIG. 10.

one case three small chromosomes, and in the other only one.

(5) Complete triploid individuals having three of each kind of chromosome have recently been found by Bridges (Fig. 10). The triploid flies are larger and coarser than normals, and also have large, rough eyes. Their eggs, as shown by genetic tests, contain all possible combinations of chromosomes, behaving as though non-disjunction takes place independently in each set of three.

Amongst the offspring of a triploid female (mated to a normal male) there is one class that has three II's, three III's, and three IV's, but with two X-chromosomes. This individual is an intersex, more like a male than a female. There is another class that has three II's, three III's, but only two IV's. It also is an intersex, but more like a female.

Thus sex itself, in this animal, is shown to be an expression of a balance between the X-chromosomes and the rest of the chromosomes. The results show that the differentials which determine sex are not confined to the sex-chromosomes alone. Some appear to be in the II- and III-chromosomes, and others in the IV-chromosome.

(*To be continued.*)

Obituary.

PROF. GIACOMO CIAMICIAN.

BY the death of Prof. Giacomo Luigi Ciamician, of the University of Bologna, Senator of the Kingdom of Italy, which occurred on January 2 of the present year, Italy has lost one of her most distinguished men of science, and modern chemistry one of the most assiduous and most successful of its cultivators.

Ciamician's work was characterised by the breadth and originality of its grasp. It ranged practically over every department of the science—spectrum analysis, electrolytic dissociation, organic synthesis by plants, chemical action of light, spatial chemistry—but it was mainly concerned with problems of organic chemistry, and it is by his labours in certain special fields of this branch that he will be chiefly remembered. One of his earliest investigations was an inquiry into the chemical nature and constitution of the resins and gum-resins—a confessedly difficult and complicated subject forty-five years ago when he first attacked it. By distilling abietic acid, the main constituent of colophony or ordinary rosin, with zinc-dust in a current of hydrogen—a reduction-process which had been already proved to be of general utility—he obtained a number of aromatic derivatives, notably toluene, *m*-ethylmethylbenzene, naphthalene, methylnaphthalene, and methylanthracene. Gum-benzoin similarly treated yielded similar products, together with small quantities of xylene. Elemi-resin also yielded toluene, and ethylmethylbenzene and ethylnaphthalene, but no naphthalene or methylanthracene. Gum-ammoniacum gave both para- and meta-xylenes and meta-ethylmethylbenzene, and the methylether of ortho-ethylphenol, but no naphthalene derivatives. These observations are of considerable interest, but they do not necessarily throw light upon the constitution of the terpene-resins, as certain of the products may be the result of secondary reactions. In fact, aldehyde-resin, obtained from ordinary aldehyde and therefore not an aromatic derivative, on reduction with zinc-dust, was found to yield ethylbenzene, meta- and para-ethyl toluene, and methylnaphthalene.

In 1881 Ciamician attacked the chemistry of pyrrole, a constituent of the fetid-smelling product obtained by heating bones in the preparation of animal charcoal, and hence termed bone-oil or Dippel's oil, from the name of the chemist who, so far back as 1711, first attempted to get an insight into its nature. This product has been known for at least four centuries, and has been the subject of repeated inquiry.

The investigation of pyrrole, first isolated by Runge in 1834, its congeners and derivatives, occupied Ciamician, at intervals, for upwards of a quarter of a century, and he published, partly alone, and partly in conjunction with Dennstedt, Weidel, Anderlini, Magnaghi, Magnanini, Silber, and Zanetti, no fewer than sixty communications on its chemistry. In 1904 he reviewed all this work in a lecture delivered to the German Chemical Society, afterwards printed in vol. 37 of its Berichte. It forms a remarkable chapter in the development of a section of organic chemistry with which Ciamician's name will always be associated He established the nature of pyrrole as a secondary amine, its carbon and hydrogen atoms forming a closed chain, the hydrogen atoms being symmetrically situated with respect to the carbon atoms, as suggested by Baeyer. Its formation from succinimide by distillation with zinc-dust, and the fact that it yields succinaldehyde dioxime by the action of hydroxylamine, conclusively established this view of its constitution.

Ciamician's work on pyrrole had many side issues. He elucidated its relations, not only to the substances with which it is associated in bone-oil, such as pyridine, into which he showed it might be converted, but also to indole and indigo. He was naturally led to the study of the products of the destructive distillation of gelatin, and, with Weidel, discovered pyrocoll, which he regarded as a quinone of the constitution

$$C_4H_3N\langle{}^{CO}_{CO}\rangle C_4H_3N,$$

or as the anhydride of carbopyrrolic acid, of which, with Silber, he prepared a number of derivatives, and eventually effected its synthesis by heating a solution of carbopyrrolic acid in acetic anhydride, when pyrocoll, with all the properties of that obtained from gelatin, sublimes.

Pyrrole derivatives are concerned in vital processes. They have been found in plants, and certain of them have been shown by Willstätter to exist among the decomposition products of chlorophyll and of hæmoglobin—one more illustration of the remarkable analogies which exist between these substances so important in their physiological functions.

Ciamician was early attracted to plant chemistry, and made important contributions to our knowledge of the nature and constitution of substances produced by photosynthetic processes in the vegetable organism. He determined the constitution of apiole, a substance found by von Gerichten in parsley seeds, and of the analogous compounds safrole, the chief constituent of the essential oil of sassafras and found in other natural oils, leaves, and fruits, and eugenol, a still more widely distributed natural product. With Silber he investigated the constituents of coto- and paracoto-bark, substances of pharmacological interest, and derived from plants growing in Bolivia and Venezuela.

A growing plant is a living laboratory in which synthetic processes may be directed, controlled, or modified, as in the human organism, by external means. In conjunction with Ravenna, Ciamician studied the effect of the introduction of various natural organic products into plants, with the view of determining their fate, or their influence on the life-history or development of the plant. They showed that plants will tolerate and utilise glucosides, such

as amygdalin, salicin, and arbutin, but will quickly die when the aromatic constituents of these glucosides are separately introduced. They found that plants are capable of transforming saligenin, benzyl alcohol, and vanillin into glucosides, saligenin, for example, being converted into salicin. They studied the effect of the inoculation of pyridine, piperidine, and pyrrole derivatives on the formation of alkaloids; they found that the amount of nicotine in the tobacco plant could be considerably increased by the introduction of dextrose. Their results lent support to the view that vegetable alkaloids have their origin in amino-acids, and that bases, such as lysine and ornithine, formed from amino-acids, are utilised by plants in the synthesis of alkaloids.

The chemical action of light has long been a special study with Italian chemists. Blessed with sunnier skies than we enjoy in these latitudes, they have had ampler opportunities than we possess to observe its effects, and, thanks to their long-continued and systematic work, a considerable body of information has been accumulated. Some of Ciamician's earliest observations had reference to this subject, and it continued to interest him to the end of his days. He noticed the conversion under its influence of quinone into quinol; of an alcoholic solution of nitrobenzene into aldehyde, aniline, and quinaldine; and of *a*-nitrobenzaldehyde into *o*-nitrosobenzoic acid, the nature of the changes and the character of the products formed being affected by the vehicle in which the substances under examination were contained, and the refrangibility of the light-rays. Unsaturated compounds tended to polymerise. An aqueous solution of acetone yielded acetic acid and methane; maleic acid was converted into fumaric acid; vanillin, piperonal, salicylaldehyde, and cinnamaldehyde yield the corresponding acids; lævulic acid forms propionic acid; many cyclo-ketones are broken down and fatty acids and aldehydes formed; benzaldehyde is resinified, and may be condensed with many different compounds; solutions of benzophenone in aromatic hydrocarbons yield benzopinacone, and the hydrocarbon undergoes condensation; camphor in dilute aqueous alcoholic solution yields acetaldehyde and campholenaldehyde; fenchone forms carbon monoxide and fenchone hydrate. Aromatic hydrocarbons in presence of water and oxygen are partly oxidised to the corresponding carboxylic acids. Pyrrole by prolonged exposure is completely decomposed, one of the products being succinimide, which may be regarded as the ketonic form of the quinol of pyrrole.

This is but a bald and imperfect summary of an intensely interesting and most important chain of observations, the full significance of which is scarcely yet realised. The potency of light has, of course, long been recognised, but no such evidence of its power to induce chemical action had hitherto been adduced as that afforded by Ciamician's work.

Ciamician was an accomplished, well-informed man, of great personal charm, whose influence on the chemistry of his epoch will long be felt. His merits were widely recognised. He was a foreign associate of the French Academy and an honorary fellow, since 1911, of our Chemical Society. He was an occasional visitor to London, and personally known to some British chemists who will long cherish his memory as an earnest and single-minded follower of the science he has done so much to enlarge and adorn. T. E. THORPE.

WE regret to see the announcement of the death on Saturday, February 18, of SIR JOHN MCCLURE, who for the past thirty years has been headmaster of Mill Hill School. Sir John McClure, who was born in 1860, received his education at Cambridge, where he took mathematics and law. From 1885–91 he acted as lecturer in astronomy and other scientific subjects under the Cambridge University Extension Syndicate, while from 1888–94 he was professor of astronomy at Queen's College, London. It was in 1891 that he received the appointment of headmaster at Mill Hill School, a post which he filled with conspicuous success for more than thirty years. The school, which was founded in 1807 for the education of Nonconformists when the older universities were not open to them, was reconstituted in 1869, and flourished for a time; but when Sir John McClure arrived in 1891 there were only sixty-one boys. He immediately set to work to develop and reconstruct the school, with the result that last year he was able to announce that the number of boys under his charge had grown to 361. Sir John McClure was also active in the cause of education outside his school. From 1904–13 he was honorary secretary of the Incorporated Association of Headmasters, and later became president, and it was mainly in recognition of these and similar services to education that he received the honour of knighthood in 1913.

ORIENTAL learning has suffered a grievous loss by the death, at the age of eighty years, of SIR ARTHUR NAYLOR WOLLASTON, K.C.I.E. Appointed to a post in the India Office at the age of sixteen, Wollaston served for forty-eight years in that Department. In 1898 he succeeded the late Mr. F. C. Danvers as registrar, and he was so successful in arranging the voluminous series of records that they became readily accessible to students. In this task he was succeeded by his pupil, Mr. W. Foster, who has done valuable work in calendaring the collection. Wollaston, in addition to his official duties, became an admirable Persian scholar, though he never had the good fortune to visit the East. He translated the Fables of Bidpai, and edited Sir Lewis Pelly's "Miracle Play of Hasan and Husain." But the work by which he will be best remembered is his great English–Persian Dictionary. At Walmer, where he resided for many years, he took an active share in the local administration.

THE death is announced of PROF. ERICH EBLER, professor of inorganic and analytical chemistry in the newly founded University of Frankfort-on-Main. Prof. Ebler, who was forty-two years of age, was appointed only in 1920, after service with the Army in the field.

Current Topics and Events.

We are glad to be able to announce that representatives of British science are included among those who have received their Majesties' invitation to the marriage of Her Royal Highness Princess Mary on Tuesday next, February 28.

Prof. F. G. Hopkins and Dr. W. H. R. Rivers have been elected members of the Athenæum Club under the rule which empowers the annual election by the committee of a certain number of persons "of distinguished eminence in science, literature, the arts, or for public service."

In a letter to Nature of May 19, 1921 (vol. 107, p. 359), Prof. Stanley Gardiner directed attention to the serious effect of the German Reparations (Recovery) Act upon scientific workers and institutions in this country in regard to the duty of 26 per cent. on German publications; Prof. Gardiner at the same time protested strenuously to the Board of Trade. He has now received a reply in which the Board states that an Order has been made under section 5 of the Act referred to granting exemption from the levy in the case of certain periodical publications in the German language. The Order, which is dated February 16, reads:—"Any article of the following description shall be exempt from the provisions of the said Act—that is to say, any article being a publication in the German language which is proved to the satisfaction of the Commissioners of Customs and Excise to be a periodical publication of a German learned society or other scientific or philosophical periodical publication." Communication should be made with the Secretary, Custom House, Lower Thames Street, E.C.3, for particulars as to the manner in which to apply for the exemption of any particular consignment.

The relatives of the late Sir Ernest Shackleton decided that the most appropriate burial-place for the dead explorer was the sub-Antarctic island of South Georgia, where he died and on which he performed the great feat of crossing the unknown ridge of mountains on his way from Elephant Island to the settlement of whalers in 1916. The body, which had been brought from South Georgia to Monte Video by Capt. Hussey, the meteorologist to the Shackleton-Rowett Expedition, was accordingly conveyed on board the British whaler *Woodville* at that port on February 15, the late explorer's birthday, and Capt. Hussey sailed with his old leader on the following morning. The Uruguayan Government, with characteristic sympathy and generosity, arranged the funeral procession as a State function, particulars of which appeared in the *Times* of February 16. The body in the rough wooden coffin made by the South Georgian whalers was taken to the English church in Monte Video, where the funeral service was read by Canon Blount. The coffin, placed on a gun-carriage and covered with the Union Jack and many wreaths, including one in bronze from the Uruguayan Government, was taken to the British Club, the British Chargé d'Affaires and many members of the British colony, including some from Buenos Aires, following. At the club the Uruguayan Minister of Foreign Affairs joined the procession, which moved on to the wharf accompanied by a guard of honour of Uruguayan Lancers, and the streets were lined with troops. At the wharf the Uruguayan War Minister delivered a sympathetic address, which was replied to by the British Chargé d'Affaires. When the *Woodville* sailed she was accompanied to the limit of territorial waters by the Uruguayan cruiser *Uruguay*, and on parting she fired a salute and ranged alongside the *Woodville*, with all hands lining the ship in farewell. The burial will take place on March 1, and a memorial service will be held in St. Paul's Cathedral on March 2.

A somewhat startling paragraph recently appeared in the *Times* giving an account of petroleum "divining" of an extraordinary nature by means of laboratory experiments carried out in France. Dr. Henri Moineau and M. Regis have apparently been at work on an apparatus for which it is claimed that by "harnessing Hertzian waves" the composition of subterranean solid, liquid, and gaseous matter may be indicated, quite irrespective of distance! Experiments are at present being carried out at the Puy du Dôme, in the Clermont-Ferrand region, and already this mysterious apparatus has detected petroleum deposits in Alsace, Saxony, Hanover, Czecho-Slovakia, Italy, the Rocky Mountains, the Allegheny Mountains, and finally in the Andes. No account whatever is given of the nature of the apparatus itself, though it is suggested that X-ray photography plays an important *rôle* in the determinations, particularly in the elucidation of underground structures. It is further alleged that with the apparatus it is possible to discern, not only oil, but also coal, minerals, and water occurring in remote parts of the world, the idea being that once such occurrences are located all that is necessary as a preliminary to successful boring is an aerial reconnaissance for the purpose of taking "X-ray photographs" of the selected areas. We cannot refrain from remarking that, although first impulse may dictate a dismissal of the matter as extravagant, present knowledge of electromagnetic wave propagation, though limited, is sufficient to promote realisation of possibilities, and caution before condemning prematurely their utilisation in the present connection.

At a celebration which took place in the chemistry lecture theatre of the Sorbonne on January 22 Prof. Henry Le Chatelier was presented with a gold medal in commemoration of his fifty years' work of scientific and technical research. The chair was occupied by M. G. Noblemaire, president of the Comité Jubilaire, who recalled the various stages in the career of the illustrious *savant* and outlined the series of remarkable discoveries made by him, most of which have received important industrial applications. Eloquent speeches were also made by M. Molliard, dean of the Faculté des Sciences, and by M. Bertin, president of the

Académie des Sciences. Prof. Trasenster, representing the University of Liège, handed Prof. Le Chatelier the diploma of engineer *honoris causa* of the "Faculté Technique Wallonne." Surrounded by eminent men of science, engineers, and students, Prof. Le Chatelier, after thanking the members of the committee, declared that he was happy "to have been able to add a few links to the solid and durable chain of scientific discoveries, science being essentially a collective work, forged by the continuous and methodical labour of the *savants.*"

THE search for the two missing men, Tessem and Knudsen, of Amundsen's Arctic Expedition who left the *Maud* in October, 1918, in the vicinity of Cape Chelyuskin carrying dispatches to Europe leaves no room for hope that they are alive. The *Times* of February 18 announces that Capt. Jacobsen, who has been searching the north-west coast of Siberia in the *Heimen*, found a note from the men near Cape Wild (long. 91° 30′ E.) to the effect that they arrived there in the middle of November, 1918, and found their provision depôt much damaged by sea-water, but that they were leaving under favourable conditions for Port Dickson, at the Yenisei mouth. Beyond Cape Wild, at a distance which Capt. Jacobsen does not specify, he found the remains of camp-fires and indications that a human body had been cremated. He believes that one of the men died there and that the survivor burnt his body lest it should be devoured by bears. No further traces were found.

THE first volume of the Dictionary of Applied Physics, of which Sir Richard Glazebrook is the editor, is announced by Messrs. Macmillan and Co., Ltd., for March, and the remaining four volumes may be expected before the end of the year. The successive volumes are to be devoted to mechanics, engineering, and heat; electricity; meteorology and metrology; optics, sound, and radiology; and metallurgy and aeronautics. The arrangement of the articles in all the volumes is to be alphabetical, and each article is written by a specialist. The list of contributors shows that the editor has succeeded in securing actual workers in each branch, and that the articles will therefore be thoroughly up to date. As the first attempt to place before the public in a convenient form the methods and results of recent research in applied physics, the Dictionary will be welcomed by all engaged in industries in which physics plays a part, as well as by scientific workers generally.

THE annual dinner of the Illuminating Engineering Society on February 10 aptly illustrated the variety of work with which the society is now concerned. Sir John H. Parsons, president of the society, presided. Sir Herbert Jackson, representing the Royal Society, proposed the toast of "The Illuminating Engineering Society," and Mr. J. B. Lawford (chairman of the Council of British Ophthalmologists) joined him in expressing appreciation of the programme of the society, notably in promoting discussion of the effect of light on the eye. The toast of "Kindred Societies" was proposed by Mr. F. W. Goodenough. Mr. T. Hardie (president of the Institution of Gas Engineers) and Mr. A. A. Campbell Swinton (vice-president of the Institution of Electrical Engineers and chairman of the Royal Society of Arts) pointed out how those associated with both forms of lighting had found a common interest in illuminating engineering. The toast of "The Guests" was proposed by Mr. L. Gaster. Mr. R. E. Graves (H.M. Chief Inspector of Factories) and Mr. William Brace (Mines Department), in responding, referred to the activities of the society in connection with industrial lighting and conditions of illumination in mines, and Mr. H. E. Blain emphasised the importance of good illumination in the interests of safety, both in relation to traffic and in industry.

THROUGH the generosity of the Fertilisers Manufacturers' Association and of the British Sulphate of Ammonia Federation, a special member has been appointed on the staff of the Rothamsted Experimental Station for the purpose of explaining the plots to farmers and others. Mr. H. V. Garner, of the School of Agriculture, Cambridge, has accepted the new post. The director, Dr. E. J. Russell, will now be glad, therefore, to arrange with secretaries of farmers' clubs, Chambers of Agriculture, and other bodies interested for visits to the plots. Among important items of interest are experiments on the manuring of arable crops, especially wheat, barley, mangolds, and potatoes; the manuring of meadow hay; the effect of modern slags and mineral phosphates on grazing land, hay land, and arable crops; crop diseases and pests; and demonstrations of good types of tillage implements, tractors, etc. At any convenient time between May 1 and October 1 there is sufficient to occupy a full day, and provision is being completed for assuring that the time shall not be lost, even if the weather turns out to be too bad to allow of close inspection of the fields.

IT will be remembered that Dr. Saleeby, writing in NATURE of December 8, p. 466, urged the importance of a co-ordinated inquiry into the action of sunlight in health and disease, under the auspices of the Medical Research Council. We are glad to see that the council has now appointed the following Committee to report upon the promotion of researches into the biological action of light with the view of obtaining increased knowledge of the effects of sunlight and other forms of light upon the human body in health or disease:—Prof. W. M. Bayliss (chairman), Mr. J. E. Barnard, Dr. H. H. Dale, Capt. S. R. Douglas, Sir Henry Gauvain, Dr. Leonard Hill, and Dr. J. H. Sequeira. Dr. Edgar Schuster is secretary of the Committee.

AT the monthly meeting of the Zoological Society of London held on February 15 twenty-four new fellows were elected to the society and thirty proposed for the fellowship. The secretary stated that the additions to the society's menagerie during January numbered 151—52 by presentation, 76 deposited, and 23 by purchase. The most important accessions included a Macedonian wolf (*Canis lupus*), a Dybowski's deer (*Cervus hortulorum*), eleven plumbeus quails (*Synaecus plumbeus*), and two angle

fish (*Pterophyllium scalare*), the last two species new to the collections. The report of the secretary recorded a considerable decrease in the number of visitors to the gardens in January as compared with the numbers of the corresponding month last year.

AT a meeting of the council of the National Institute of Agricultural Botany held on February 9 the first election of fellows of the institute took place. A hundred and ten candidates were elected, among whom were the following:—H.R.H. the Duke of York, the Prime Minister, the Duke of Bedford, the Marquess of Crewe, the Earl of Ancaster, the Earl of Derby, the Earl of Crawford, Viscount Milner, Lord Clinton, Lord Bledisloe, Lord Ernle, Sir Gilbert Greenall, Sir Harry Verney, Sir Matthew Wallace, the Hon. E. G. Strutt, the Right Hon. E. C. Pretyman, M.P., the Right Hon. Sir A. Griffith-Boscawen, Sir Thomas Middleton, Mr. Charles Adeane, Mr. Samuel Farmer, Mr. R. R. Robbins, and Lady Margaret Boscawen.

THE officers and other members of council of the Malacological Society of London for the ensuing year were elected on February 10 as follows:—*President:* Mr. A. S. Kennard. *Vice-Presidents:* Mr. J. R. le B. Tomlin, Prof. A. E. Boycott, Mr. G. K. Gude, and Mr. C. Oldham. *Treasurer:* Mr. R. Bullen Newton. *Editor:* Mr. B. B. Woodward. *Secretary:* Mr. A. E. Salisbury. *Other Members of Council:* Dr. A. H. Cooke, Mr. H. O. N. Shaw, Lt.-Col. A. J. Peile, Mr. T. Iredale, Dr. E. W. Bowell, and Mr. Hugh Watson.

ON Thursday next, March 2, Prof. H. M. Lefroy will deliver the first of two lectures at the Royal Institution on (1) "The Menace of the Insect Pest" and (2) "The Balance of Life in Relation to Insect Pest Control." On Saturday, March 4, Sir Ernest Rutherford will begin a course of six lectures on radioactivity. The Friday evening discourse on March 3 will be delivered by Dr. C. Morley Wenyon on "Microscopic Parasites and their Carriers."

DR. W. BATESON, director of the John Innes Horticultural Institution, Mostyn Road, Merton, S.W.19, is giving a demonstration of the genetics of *Primula sinensis* at the institution to-day, February 23, at 3 p.m. All interested in the subject are invited, and in particular those who attended Dr. Bateson's lectures on genetics in November last. Admission is free, without ticket.

THE ninth election to Beit fellowships for scientific research will take place in July next. Applications must be received by the Rector, Imperial College of Science and Technology, South Kensington, S.W.7, not later than April 19. Forms of application and all information respecting the fellowships are obtainable from the Rector of the Imperial College of Science and Technology upon written request.

THE first award of the Meldola medal, referred to in NATURE of January 12, p. 49, has been made by the council of the Institute of Chemistry, with the concurrence of Dr. Percy E. Spielmann, representing the Maccabæans, to Dr. Christopher Kelk Ingold.

Our Astronomical Column.

DETONATING FIREBALL IN SUNSHINE.—Mr. W. F. Denning writes that this object observed by him on February 7 at 3.55 p.m. appears to have been seen by comparatively few observers, although the loud detonations which followed it were heard by large numbers of people, chiefly in Warwickshire, over which county the fireball passed. It seems to have caused the loudest reports near the middle section of its flight, in the region of Quinton, Feckenham, Mere Hall, and Droitwich. At some places there was only one sound heard, at others two, but all the observers agree that the concussion and vibration were of startling intensity. The detonations were heard along a line directed from S.E. to N.W. The radiant point of the meteor was at $60° - 11°$, and the height from 56 to 32 miles; the length of luminous flight was 82 miles, and velocity about 10 miles per second. The position of the object was from over Oxfordshire to Shropshire.

MOVEMENTS IN SPIRAL NEBULÆ.—In this column for January 12 reference was made to the movements in spiral nebulæ which Dr. Jeans described at the Royal Astronomical Society when exhibiting slides sent by Dr. van Maanen. Dr. van Maanen has now published the fifth paper on this subject in the issue of the *Astrophysical Journal* for December last, showing the results of his investigation with regard to the spiral nebula Messier 81. This paper contains the evidence on internal motions derived from the four nebulæ which Dr. van Maanen has now measured, namely, M 101, 33, 51, and 81, and he summarises the results in a table of which the following is an abstract. The second column gives the interval in years between pairs of photographs he has compared, and the following four columns the motions as indicated at the heads of the columns. The last column gives the number of nebular points the positions of which were independently measured:—

(*Units for Motions* 0·001″.)

Object	Interval in years	Rotational	Radial	Stream	Transverse	No. of nebular points
M 101	5	+21	+ 5	+21	0	87
M 101	9	+20	+ 6	+22	− 3	69
M 101	15	+12	+ 7	+14	+ 2	46
M 33	10	+20	+ 6	+24	− 2	30
M 33	5	+14	+12	+18	+ 4	21
M 51	11	+19	+ 8	+21	+ 3	79
M 81	6	+20	+17	+25	+16	52
M 81	11	+38	+13	+39	+ 7	104

It will be seen that all pairs of plates show the same type of motion, and, as Dr. van Maanen points out, the agreement in the values of the motion for each nebula derived from different pairs of plates is as satisfactory as could be expected. In addition to the rotational components, which correspond to the periods in the order of the nebulæ in the table, namely, 85,000, 160,000, 45,000 and 58,000 years, they all show a large outward radial component. The close agreement of the displacements in direction with the spiral arms of the nebulæ suggests, as he states, "a realisation of the motions described by Jeans in 'Problems of Cosmogony and Stellar Dynamics.'"

Research Items.

Juvenile Delinquency.—In *Psyche* (vol. 2, No. 3) Dr. Cyril Burt discusses the causes and treatment of juvenile delinquency. In studying crime, he points out, we encounter at the outset the fact of multiple determination. Crime in any given person usually proves to be attributable, not to some one all-explaining cause such as "inborn criminality," but to a converging number of alternating factors. Usually some predominating factor can be singled out as chiefly responsible, which factor may be a legitimate label for classification, but in treatment it is never safe to deal with one factor only, however crucial it may be. In all cases it is necessary, for any scientific appreciation of the disturbance, to make a complete and comprehensive survey of the whole child and his surroundings; we must know the child's physical characteristics as well as its emotional and intellectual endowment. The author, while assigning a due position to mental defectiveness, does not support the view that all or most criminals are mentally defective. Various methods of diagnosis and of treatment are discussed. The article will be extremely valuable to all those who, whether from the point of view of theoretical psychology or of practical life, are interested in the individual and social consequences of delinquency.

Craniometry in the British Isles.—Prof. F. G. Parsons has done good service to anthropometry by collecting in the February issue of *Man* all the available records of the cephalic index to be found in these islands. The record of 3000 criminals is of special interest, as they show the very high cephalic index of 785, and the size of their heads is very low. This suggests that our recent immigrants from Central Europe have contributed even more than their fair share of crime. It is also remarkable that the average index of a group of Cambridge students is 796 as compared with the Oxford average of 780; possibly some mistake has crept into the arithmetic, but the question deserves further investigation. Other interesting deductions from these figures are that the average head-shape of people in England differed very little between Saxon times and the eighteenth century, the trifling variations being probably due to immigration from the Continent; and that these records do not supply any reason to believe that the size of the modern Englishman's head is increasing with its increasing rotundity; in fact, both the Saxons and the Long Barrow folk, from the fusion of whom most of our blood is derived, seem to have had rather larger heads than the average modern Englishman, and there is no reason to believe that physically they were larger men. Unfortunately, these records, confined to the cephalic index, take no account of head height, which is a serious loss. Further, this collection, large as it is, is inconclusive when compared with a population of some forty millions. In the past, as, for instance, in India, the evidence from craniometry has led to unfounded theories because the number of the subjects was insignificant as compared with the total population. If it is to succeed in justifying its claims, provision must be made for a much larger number of measurements, and these must not be confined to the cephalic index.

Safflower-seed Oil.—Bulletin 124 of the Agricultural Research Institute, Pusa, contains an account of safflower oil. Safflower (*Carthamus tinctorius*, L.) is widely cultivated in India, both as an oilseed and, to a much smaller extent, for the reddish dye (carthamin) in the flowers. The crop is extensively grown in the driest areas of the Deccan for its oilseed. The oil is edible when clarified, and is used as an adulterant for butter. The sweet-oil of Bombay is made by mixing safflower, earth-nut, and *til* seeds and expressing the oil. After boiling, safflower oil forms a gelatinous mass, and it is a drying oil. This form is used as "roghan," or Afridi wax, for the preparation of wax-cloth. The oil is also suitable for the manufacture of soap. It is suggested that safflower-seed oil could become a valuable commercial product on the home markets.

Date Cultivation in the 'Iraq.—Under the auspices of the Agricultural Directorate, Ministry of the Interior, Mesopotamia (Memoir 3, 1921), Mr. V. H. W. Dowson has published a very interesting and valuable report on date cultivation on the Shat el Arab, the river which conveys to the Persian Gulf the joined waters of the Euphrates and the Tigris. The Shat el Arab is the most important area of date cultivation in the world; both banks are lined with date-gardens for a distance of 108 miles, with an average width on either side of about a mile, representing about 138,000 acres. In the 'Iraq the date-palm flourishes wherever it is watered and cared for, from Ana on the Euphrates and Samara on the Tigris southwards; north of these towns the winters are too cold. Mr. Dowson describes in detail the methods of cultivation and marketing, and also enumerates the chief uses of the palm and its products—in the last instance he refers to an old Tamil song which enumerates eight hundred and one uses of the Palmyra palm, and remarks that the number of uses of the date-palm and its products is probably but little short of this number. Compared with many fruit-trees, the date-palm suffers but little from disease; its one important enemy is the larva of a Gelechiid moth, the adult of which is unknown. Preventive measures against the ravages of this pest, which causes the young green dates to turn brown and drop to the ground, have still to be devised. In a second part of the memoir the author gives a statistical summary of his investigation into the yield of the different varieties, and in a third part (in preparation) he will deal generally with the varieties of date-palms of the 'Iraq, which includes also the Bagdad area, the next largest date-cultivation centre in the country, comprising about twenty miles of date-gardens lining both banks of the Tigris. The memoir is illustrated with numerous photographic reproductions.

British Mycological Society.—In pt. 3 of vol. 7 of the Transactions of this society Mr. Petch, of Ceylon, continues his studies in entomogenous fungi, writing learnedly of the Nectriæ parasitic on scale insects. A number of new species are described, but it is very unfortunate that no cultural data are given. An interesting account of the recently founded Imperial Bureau of Mycology, with a suggestive *résumé* of its functions, is contributed by the director, Dr. E. J. Butler. The establishment of this bureau is somewhat of an epoch-making event in phytopathology, and all support possible should be rendered to it. Messrs. Brooks and Searle give an account of the fungi responsible for certain tomato diseases, emphasising what should be so obvious: the necessity of cultural data in specific determinations. There are also an interesting paper by Miss Mounce on homothallism and the production of fruit-bodies by

monosporous mycelia in the genus Coprinus, and a note by Mr. Collet describing viability in *Fumago vagans* after sixty-seven years' preservation as a herbarium specimen. The issue is well produced and illustrated by five plates, two of which are beautifully coloured.

SILICIFIED PLANT REMAINS.—The Middle or Lower Devonian flora discovered by Dr. Mackie at Rhynie, in Aberdeenshire, was generally reviewed by Prof. F. O. Bower in 1920 (NATURE, vol. 105, pp. 681 and 712). Dr. Kidston and Dr. W. H. Lang (Trans. Roy. Soc. Edin., vol. 52, pt. 4, 1921) now describe the thallophytes occurring in the remarkable silicified peat-bed, and discuss the conditions of accumulation. The sequence is due to continued growth on a land-surface that was at times submerged in lake-waters impregnated with silica. A volcanic source is suggested for the silica, and it is pointed out that the growth of cyanophaceæ and bacteria in modern hot springs is known to promote a deposition of colloidal silica. We may note that Prof. W. N. Benson (Proc. Linn. Soc., New South Wales, vol. 45, p. 315, 1920) refers the silicification of remains of gymnosperms in Carboniferous beds on Mount Cobla, New South Wales, to contemporaneous hydrothermal solutions associated with the deposition of keratophyric tuffs. In view of climatic changes in the past, the possibility of the spread of siliceous waters derived from laterisation must not, of course, be overlooked.

AUSTRALIAN METEOROLOGY.—Meteorological statistics for the Australian Colony of Victoria have recently been published, based on all the available records obtained at 1046 official stations from January, 1856, to December, 1907. They have been prepared under the direction of Mr. Pietro Baracchi, Government Astronomer from 1895 to 1915. Observations were commenced at Melbourne in 1840 and continued until 1851, when, in consequence of Government changes, there seems to have been a break for about four years. From 1855 observations were made at Melbourne and at some twenty stations in different districts of the Colony. All observations were controlled by the authorities at Melbourne Observatory until 1907, when the meteorological duties were taken over by the Government of the Commonwealth of Australia under the control of the Commonwealth Meteorologist, Mr. H. A. Hunt. The observations included in the volume received are a summary of results to 1907, when the responsibility of Melbourne Observatory ceased. This volume of the early Australian weather observations is of great value as affording data for seasonal changes and possibly showing meteorological irregularities of interest in connection with more recent observations. A detailed history is given of the development of the system of observing and showing the requirements and value of meteorological observations, especially a thorough knowledge of rainfall distribution. Many details given in the introduction are of extreme value, and show most thorough supervision and great alertness as to the utility of special observations. At Melbourne observations are given for a period of fifty years. The mean and extreme values for the several elements and for the different regions of observation are of high scientific value.

STANDARD CELLS OF LOW VOLTAGE.—In the issue for November, 1921, of the Proceedings of the Physico-Mathematical Society of Japan Mr. J. Obata describes the investigation he has carried out on the possibility of constructing standard cells of low voltage for testing purposes. Nine types of cell have been studied, in all of which cadmium or cadmium amalgam formed the negative, and cadmium or lead amalgam the positive pole. The electrolytes were solutions of lead or cadmium sulphate, chloride, bromide, or iodide, and the cells were given the H form. The two cells which proved most suitable for standards were the cadmium amalgam/cadmium iodide/lead iodide/lead amalgam cell with an electromotive force at 20° C. of 0·09838 volt and a temperature coefficient of 0·00024 volt per degree, and a cadmium amalgam (10 per cent.)/cadmium sulphate solution/cadmium amalgam (dilute) cell with an electromotive force of about 0·01 volt and a temperature coefficient of about 0·0004, according to the strength of the dilute amalgam.

MAGNESIUM IN ORGANIC CHEMISTRY.—Mr. H. Hepworth describes in the issue of the Journal of the Society of Chemical Industry for January 16 the recent applications of magnesium in organic chemistry. The "Grignard reaction," since its discovery in 1900, has found numerous applications in organic synthesis, and this paper is an interesting *résumé* of much recent work. The following examples will serve to illustrate the new lines of research made possible by the use of magnesium compounds. *Cyclo*pentamethylstannines, in which the ring contains an atom of tin replacing carbon, have been obtained. Tin diaryl-compounds exhibit an intense colour. Lead tetra-alkyls, lead triaryls, apparently analogous to triphenylmethyl, and mixed tin and lead compounds have been prepared, and *l*-phenylchloroacetic acid is converted by magnesium phenyl bromide into *d*-diphenylsuccinic acid. The use of ether in preparing the Grignard reagent is not essential, but the early view that an additive compound was formed seems to have received confirmation by the isolation of a crystalline compound, $2(C_7H_7)_3PO,CH_3MgI$, when tribenzyl phosphine oxide is used instead of ether, and of crystalline $(C_5H_{11})_2O,MgCH_3I$ with amyl ether. Instead of the oxonium structure for such compounds, a formula in which magnesium is the central atom with co-ordination number 4 has been proposed, the ether being attacked by subsidiary valencies.

VIBRATIONS OF VEHICLES.—According to an article by M. A. Boyer-Guillon in the November issue of the Bulletin of the Société d'encouragement pour l'Industrie nationale, the Auclair and Boyer-Guillon accelerometer is to be used in the near future in a detailed study of the oscillations, shocks, or vibrations to which the rolling stock of the French railways is subjected. The Automobile Club of France and the Society of Architects propose also to use it in a study of the vibrations of buildings. The instrument has already led to the solution of problems connected with the failure of machines apparently well designed for the stresses they were expected to withstand. In most cases it has shown that the accelerations to which parts of the machines were subjected were far in excess of those contemplated. Used on autocars in Paris streets it gives the vertical accelerations on irregular wood and on good stone pavements as between 6 and 7 metres per sec. per sec. at a speed of 27 km. per hour. The instrument itself consists of a heavy mass held up by springs attached to the ends of rods which project radially from it. The springs are of graduated strengths, and each holds the rod to which it is attached against a stop with which it makes electrical contact until the down acceleration breaks the contact, and the break is registered on the revolving drum of a chronograph.

The Standardisation of Radium Ampoules for Therapeutic Use.

AN apparatus for the routine standardisation of ampoules containing radium compounds and emanation by the γ-ray ionisation method was installed recently at the Institut Curie. It consists, as

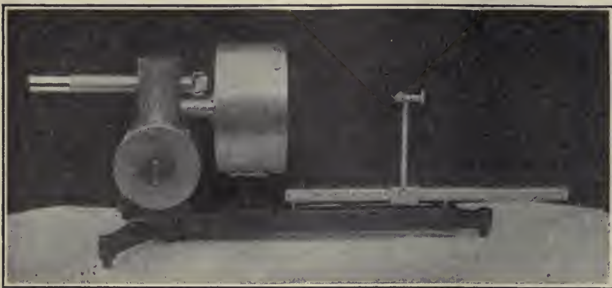


FIG. 1.—Apparatus for the standardisation of radium ampoules (one-tenth full size).

shown in Figs. 1 and 2, of a screened ionisation chamber A connected directly to a gold-leaf electroscope B. The ampoule to be tested is placed in an aluminium tray on the support C, which can be slid along a graduated rule D. The intensity of the ionisation current is deduced from the rate of fall of the gold-leaf.

A novel feature of the apparatus is the method of charging the electroscope by means of a variable multicellular condenser E, which obviates the need for a high-voltage battery.

The fixed plates of the condenser are connected to the frame, whilst the movable plates are mounted on a spindle actuated by an ebonite knob. When the condenser is in the position of maximum capacity a projecting finger F brings the movable plates momentarily into contact with the stem H, to which is connected a low-voltage battery (10–20 volts). On turning the movable plates through 180° the same finger comes into contact with another stem J connected to the electroscope; at this instant the capacity of the condenser is at its minimum and the potential proportionately increased (about thirty times).

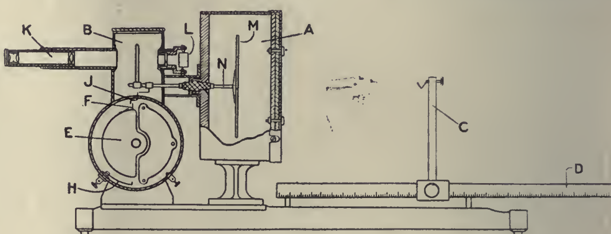

FIG. 2.—Sectional view.

The gold-leaf is observed by means of a microscope K the eyepiece of which is fitted with an angular scale; a small mirror L serves to illuminate the field of the microscope. The ionisation chamber consists of a cylindrical brass box containing a thin aluminium disc M, which is connected to the electroscope through the amber-insulated rod N. The end of the box facing the ampoule is closed by a screen consisting of two lead plates each 5 mm. thick.

A modification of the apparatus is used for measuring the radio-activity of ores, earths, etc. The electroscope, the charging condenser, and the substance to be tested occupy separate compartments of a cylindrical brass box. The radio-active substance is placed on a tray immediately underneath a rounded stem, the upper end of which forms the pillar of the electroscope. The latter is charged by means of a variable condenser identical with the one previously described, but it can, if desired, be charged independently or connected to a separate ionisation chamber. The electroscope is "earthed" by turning a milled head.

Both instruments were designed by M. Holweck, of the Institut Curie, in collaboration with the manufacturer, M. Beaudouin, Paris.

Life-cycles of Bacteria.

IN a preliminary communication published in 1916 Dr. Löhnis expressed the view that all bacteria pass through a definite life-cycle, and the present publication[1] is an extensive review of the literature in support of that contention. The volume also includes a chapter on methods, an extensive bibliography, and more than 350 microphotographs of the forms observed.

Briefly, the life-cycle is as follows:—Under certain conditions the cells come together and fuse, forming an amorphous mass—the symplastic stage—in which the protoplasm undergoes a thorough mixing. The symplastic stage is formed not only in cultures in artificial media, but, in the case of the pathogenic organisms, in the body of the host as well. It forms the connecting link between the various subcycles of which the life-cycle of the organism may be composed. All kinds of vegetative cells, as well as all the varieties of reproductive organs described by the author, can give rise to the symplastic stage. From the symplasm the so-called regenerative units always arise, and these either grow into new cells or several of them unite to form new cells directly.

Six distinct types of reproductive organs have been described by the author. These are:—(1) Gonidia, two to four or more in each cell. They are generally motile and slightly more resistant than vegetative cells. Many are filter passers. They grow into vegetative cells. (2) Regenerative bodies, distinct from regenerative units. They are spherical, oval,

[1] Part 1, Review of the Literature (1838–1918). By Dr. F. Löhnis. National Academy of Sciences, Washington, vol. 16, second Memoir. Pp. 252+41 plates.

pear- or kidney-shaped or more or less irregular, rod-shaped, and branched. They are readily stainable, generally motile, and fairly resistant. They may multiply by fission or budding, are formed from vegetative cells or from the symplasm, and may give rise to vegetative cells or to the symplastic stage. (3) Exospores, unstainable regenerative bodies. (4) Endospores, produced by vegetative cells or by regenerative bodies. Conditions for formation are similar to those for the formation of regenerative bodies. (5) Arthrospores, easily stainable, but withstand drying better than heating. They are formed by the segmentation of vegetative cells and transformation of the joints into fairly resistant spherical bodies. (6) Microcysts, very similar to arthrospores. They are formed by vegetative cells growing and becoming spherical with a thickened membrane. After a rest period they may become vegetative cells, germinate like spores, or may break up into two, three, or four segments, which become vegetative cells. In addition to their reproductive function exospores, endospores, arthrospores, and microcysts are, in the first place, resting-stages.

Besides the formation of the symplasm a second mode of interaction between the protoplasmic bodies in bacterial cells has been observed. This consists in the union of two or more cells, and is termed "conjunction" by the author. Conjunction is most common in cultures two to four days old, and generally precedes the formation of gonidia, reproductive bodies, exospores, and endospores.

The publication brings together an overwhelming amount of evidence as to the existence of the various forms distinguished by the author. The arrangement of these forms in the life-cycles of the bacteria is a point on which further information is desirable, but this will, doubtless, be provided in the later publication in which the observations of the author are to be dealt with in detail. From the point of view of the student of bacterial morphology the publication must be regarded as one of first-rate importance. The general worker on bacteriological problems will also find in it much information of a highly valuable nature, and doubtless will be able to confirm the existence of many of the forms observed from the results of his own experience.

Miners' Lamps.[1]

OF late years there has been a tendency on the part of makers of miners' safety lamps to employ thin sheet-metal, perforated with holes of small diameter, to serve the same purpose as wire gauze—that is to say, with holes large enough to admit of the passage of the necessary volume of air through them, but small enough to arrest the passage of flame. It will be recalled that the lamp invented by George Stephenson depended upon perforated sheet-copper for its impermeability to flame. A further innovation that has recently been gaining ground is the addition of a short glass cylinder, known as the "combustion tube," to the lower end of a metal chimney suspended directly above the flame of the lamp. This contrivance promotes a better circulation of air in the lamp, keeps the products of combustion separate from the incoming air, and, as a consequence, produces a brighter flame and enhances the lighting power of the lamp.

Metal chimneys have long been employed with this object, notably in the Mueseler lamp—the only kind of safety lamp permitted in Belgian mines—but as the bottom of the metal chimney cannot be brought lower down than the top of the flame without obstructing the light, the benefit derived from their use is limited. In this respect the glass extension is distinctly beneficial.

[1] Mines Department. Miners' Lamps Committee. Memorandum No. 4: Record of research on the passage of flame through perforated plates and through perforated tubes of small diameter. Pp. 12+6 plates. (H.M.S.O.) 9*d*. net. Memorandum No. 5: Record of research on the passage of the flame of an explosion from within miners' lamps fitted with chimneys. Pp. 12. (H.M.S.O.) 6*d*. net.

Having regard to the changes of this kind which were taking place in the construction of safety lamps, the Home Secretary appointed the Miners' Lamps Committee in 1919 to inquire into, and report on, various questions relating to safety lamps, and the Secretary for Mines re-appointed the same Committee in January, 1921. Up to the present the Committee has issued five Memoranda, of which the last two, Nos. 4 and 5, issued in the end of last year, deal with the use of perforated metal plates and chimneys respectively.

The experiments described in Memorandum No. 4 were made to ascertain the relative resistance to the passage of flame possessed by metal plates of various thicknesses perforated with holes of various diameters; and those described in Memorandum No. 5 to ascertain the relative resistance of chimneys of various lengths and diameters at top and bottom and extending to higher or lower levels above and below the wire gauze diaphragm by which they are supported.

The results are tabulated in both memoranda and in the letter to the Secretary for Mines which accompanies each the chairman of the Committee makes certain recommendations and suggestions founded on these results. The total cost of the Committee's inquiry to date (November, 1921) is given as 550*l*.

Pébrine in Silkworms.

IN an interesting report on pébrine in silkworms in India (Memoirs Dept. Agric. in India, Bacteriological Series, vol. 1, No. 8, November, 1920, pp. 75, 26 plates), Mr. C. M. Hutchinson gives an account of experimental work on methods of infection. He found infected ova in the pupal ovary, and the infection is traced in the egg, larva, and pupa—and recounts the life-history of the causal organism, *Nosema bombycis*. The Pasteur method of searching for the organism, devised more than fifty years ago, consists in crushing the body of the moth in a mortar, and examining, under a magnification of about 600, a small fraction of the resulting powder in a drop of water, to ascertain if the characteristic spores of Nosema are present. This method, according to the author, has not been attended in India with any approach to the measure of success which has been attained in Europe. The chances of non-detection of infected moths, and the risk of spreading the spores (due to careless application of the method) in the rooms used for examining the moths, are considerable—the author states that he has seldom failed to find Nosema spores in the floor dust from these rooms, even in cases where the floors were of concrete. In Europe a period of several months elapses between oviposition by the moth and hatching of the eggs, so

that the examination of the moths can be undertaken when they have undergone natural desiccation, and the Nosema, if present, is likely to be in the form of the readily recognisable spores. In India the eggs hatch out within eight days after they are laid, and during this period all the moths must be examined. Rapid desiccation prevents the Nosema forming spores, and the number of spores present in a rapidly dried moth may be so small as to escape detection by the Pasteur method. The author's revised method, depending on the fact that infection is chiefly in the chyle stomach, is to remove with needles a portion of this organ to a slide, rub it up in water, and examine it microscopically. Incidentally he remarks on the inefficiency of the copper sulphate solutions usually employed for sterilising rearing houses and appliances in Bengal, but he found that formaldehyde, employed as vapour or in 1 per cent. solution, completely destroyed the infective power of Nosema spores. A hopeful line of inquiry seems to be opened up by experiments which indicate that resistance to infection is increased by hill rearing.

University and Educational Intelligence.

BIRMINGHAM.—A post-graduate course of lectures on "Medical Aspects of Crime and Punishment" has been arranged.

The council of the University has appointed Mr. Alfred Piney to be lecturer on pathological histology.

Acting on the recommendation of the Senate, the council has approved of the following grants in aid of research for the current year:—Physics, 100*l.*; chemistry, 250*l.*; and zoology, 200*l.*

The Vice-Chancellor, Treasurer, Principal, and Vice-Principal have been appointed representatives of the University for the Conference of Universities to be held in London on May 13 next.

CAMBRIDGE.—On the recommendation of the General Board of Studies it has been decided that Mr. C. G. Lamb shall be appointed reader in electrical engineering, and that, subject to confirmation by the Special Board for Mathematics, Sir Gerald Lenox-Conyngham shall be appointed reader in geodesy.

It is proposed to confer the honorary degree of Sc.D. upon Baron A. A. A. von Hügel, Trinity College, late curator of the Museum of Archæology and Ethnology.

A visiting fellowship of the annual value of 2000 dollars, tenable for not more than three years, has been founded at Princeton University by Mr. William Cooper Procter for residential study and investigation in the Graduate College of Princeton University. An unmarried male graduate who is a citizen of this country, and not more than thirty years of age, is eligible for appointment, and the visiting fellow must give himself wholly to study and investigation in one of the purely liberal arts and sciences while holding the fellowship. Applications must be made to the Vice-Chancellor not later than the end of March.

It is notified that the Royal Commission for 1851 has decided to establish certain senior studentships of the value of 400*l.* a year, for which nominations may be made by the University of Cambridge, amongst others. Applications will be made through the professor or head of a laboratory or department under whom the candidate has already carried out research.

The Royal Agricultural Society has offered for the Agricultural School at Cambridge the income of the Hills Bequest for the investigation of the value and uses of the rarer forms of ash in the cultivation of crops.

LEEDS.—The council of the University has appointed Mr. A. Wormall demonstrator in biochemistry.

LONDON.—The following doctorates have been conferred:—*Ph.D.* (*Science*): Mr. H. T. Flint, for a thesis entitled "Integration Theorems of Four-dimensional Vector Analysis"; Mr. R. J. Ludford, of University College, for a thesis entitled "Studies in Gametogenesis: Pt. 1, Contributions to the Study of the Oogenesis of Patella, containing the Mitochondria and Gogli Apparatus in relation to Vitellogenesis in Patella; Pts. 2 and 3, Dictyokinesis in Germ-cells, and the Gogli Apparatus during Cell-division"; Mr. H. Moore, for a thesis entitled "The Season-cracking of Brass and other Copper Alloys"; and Mr. S. H. Tucker, for a thesis entitled "Carbazole."

ST. ANDREWS (UNITED COLLEGE).—The Gray prize in logic for an essay on Kant's "Deduction of the Categories" to Mr. Norman McLeish, and the Tyndall Bruce logic prize for an essay on "The Conception of Substance" in Descartes, Locke, Berkeley, and Hume to Mr. Norman McLeish.

THREE fellowships, each of the yearly value of 200*l.*, tenable for two years, are offered by the University of Wales to graduates of that University. Information respecting the fellowships can be obtained from the Registrar, University Registry, Cathays Park, Cardiff. The latest date for the receipt of applications for the fellowships is May 31 next.

MR. L. P. W. RENOUF, assistant lecturer in zoology in the Technical College, Bradford, has recently been elected to the professorship of zoology in University College, Cork. Prior to his appointment at the Technical College, Mr. Renouf was lecturer and examiner in zoology in the University of Glasgow and director of the Bute Laboratory and Museum.

THE annual general meeting of the Association of Technical Institutions will be held at the Leathersellers' Hall, St. Helen's Place, London, E.C., on Friday and Saturday, March 3 and 4. On the Friday morning the president, Viscount Burnham, will introduce the president-elect, the Right Hon. Walter Runciman, who will deliver an address. Papers to be presented are:—"Diplomas," Dr. Clay; "Certificates for Evening Students," Principal Hogg; and "A Mechanical Engineering Diploma," Brig.-Gen. Mowat. Sir Alfred Keogh, Rector of the Imperial College of Science and Technology and a past-president of the association, will attend the meeting on Friday afternoon and speak on the subject of diplomas for higher technical education and work of a university standard.

THE report for 1921 of the Association of Science Teachers contains the findings of a sub-committee appointed to consider the new regulations relating to the examination for the clerical class of the Civil Service. Referring to the science syllabus, the committee is of opinion that, in view of the fact that pupils of secondary schools are expected to take the First School Examination at the age of 16½ years, it is to be regretted that the science syllabus in the Civil Service regulations is not more in accordance with that adopted for the First School Examination; further, that teaching along the lines laid down in the new Civil Service syllabus would tend to the acquisition of a superficial knowledge of useful facts in modern science without necessarily affording a training in scientific method. The report also includes an account of the general meeting of the association held in London on January 3 last, and referred to in NATURE of January 12, p. 57.

Calendar of Industrial Pioneers.

February 23, 1860. Joseph Miller died.—Trained as a mechanical engineer at Boulton and Watt's, Miller in 1822 with Barnes established one of the most successful marine engineering works on the Thames. He was a promoter of screw propulsion, and for H.M.S. *Amphion* built the first set of direct-acting screw engines placed below the water-line.

February 24, 1815. Robert Fulton died.—Famous as the pioneer of steam navigation in the New World, Fulton was born in 1765, and in early life attained success as an artist. Afterwards in England and France he turned to mechanical pursuits; in 1800 he constructed a submarine, and in 1803 experimented with a steamboat on the Seine. He returned to America in 1806, and the following year built the *Clermont*, which, driven by an engine constructed by Boulton and Watt, ran successfully between New York and Albany. Among other vessels built by him was the *Demologos*, the first steam man-o'-war.

February 24, 1875. Marc Seguin died.—A nephew of the aeronaut Montgolfier, Seguin was the first to construct an iron-wire suspension bridge and one of the earliest of French railway engineers. In 1827 he invented the tubular boiler, and the same year applied it to a locomotive for the railway from St. Etienne to Lyons. He also made scientific investigations and endeavoured to develop the mechanical theory of heat.

February 26, 1834. Alois Senefelder died.—The inventor about 1798 of the art of lithography, Senefelder, who in his youth was connected with the stage, was led to his discovery through seeking for a cheap method of reproducing his comedies. He established a lithographic establishment at Munich, and afterwards was Director of the Bavarian Royal Lithographic Office.

February 27, 1794. Jean Rudolphe Perronet died.—Perronet has been called the Telford of France. From the office of the City Architect of Paris he entered the Government service, and in 1747 became the first director of the Ecole des Ponts et Chaussées founded by Trudaine. He was the first to introduce bridges with level roadways, and among his most notable works was the bridge across the Seine at Neuilly.

February 27, 1913. Sir William Henry White died.—From an apprentice at Devonport Dockyard White rose to be Chief Constructor of the Navy, a post he held from 1885 to 1902. During this period he was responsible for the construction of 245 vessels costing about 100,000,000*l*. A great master of his profession, he added much to the literature of naval architecture, held the presidencies of various technical societies, and was instrumental in forming the Royal Corps of Naval Constructors.

February 28, 1875. Sir Goldsworthy Gurney died.—One of the pioneers of the steam road carriage, Gurney practised as a surgeon at Wadebridge and then in London. He was the inventor of the Drummond light, the steam blast, and a water-tube boiler, and in 1829 went from London to Bath in a steam-driven carriage at 15 miles an hour.

March 1, 1911. Robert McAlpine died.—McAlpine is regarded as the father of wood-pulp paper. Emigrating from Scotland to Massachusetts at the age of sixteen, he mastered the business of paper-making, and in 1867 produced the first sheet of paper made from ground wood-pulp, the initial step in the production of abundant supplies of cheap paper.

E. C. S.

Societies and Academies.

London.

Royal Society, February 16.—Sir Charles Sherrington, president, in the chair.—L. **Hill**, D. H. **Ash**, and J. A. **Campbell**: The heating and cooling of the body by local application of heat and cold. When the hands are heated or cooled by water the amount of heating or cooling is large, but not constant for a given range of temperature. The degree of heating or cooling is obtained from the temperature of the skin over the median vein at the elbow, the thermometer used being coiled and insulated from the air. Loss of 20 to 25 kilo-calories of heat from the hands in thirty minutes, *i.e.* a loss almost equal to the basal metabolism, does not appreciably affect the body metabolism.—J. B. **Cohen**, C. H. **Browning**, R. **Gaunt**, and R. **Gulbransen**: Relationships between antiseptic action and chemical constitution, with special reference to compounds of the pyridine, quinoline, acridine, and phenazine series. Certain acridine derivatives, salts of diamino-acridine and the methochloride of this base, are extremely potent antiseptics. Pyridine and quinoline derivatives ("fragments" of the acridine molecule), a number of acridine derivatives, and some phenazine compounds were also investigated, but none approximate to diamino-acridine in antiseptic properties. Dealing with the acridine group, the presence of amino-groups increases antiseptic power, and effectiveness in serum is a characteristic of compounds with unsubstituted amino-groups, and especially of their methochlorides. Other radicals replacing the methyl group in the methochloride do not alter the antiseptic action, but substitution of alkyls in the amino-group tends to diminish antiseptic action, while acetylation or replacement of the amino-group destroys it. Antiseptic action on organisms of different types shows marked irregular variation.—D. T. **Harris**: Active hyperæmia. The lingual nerve contains true vaso-dilator and the sympathetic vaso-constrictor fibres; both are equally independent of the intervention of metabolites. Experiments show that increased blood-supply during muscular activity is due entirely to the products of metabolism, and of the metabolites estimated carbon dioxide and α-hydroxy organic acids were increased. Vaso-dilator nerves are concerned with the control of body temperature; active hyperæmia in the dog's tongue may be induced by reflex excitation of the vaso-dilator nerves through the stimulation of heat receptors in the skin.—B. B. **Sarkar**: The depressor nerve of the rabbit. The depressor nerve of the rabbit is connected in part with a special collection of ganglion-cells in the vagus, distinct from the ganglion of the trunk, which may extend into the superior laryngeal or the vagus trunk. These cells probably give rise to the afferent fibres of the depressor. The nerve is usually formed by two branches, one from the superior laryngeal and one from the vagus, and is connected with the inferior cervical ganglion, the root of the aorta, and the base of the heart. The left nerve of the pair is generally larger and contains more fibres than the right. The depressor contains medium-sized and very fine myelinated fibres, and others which are non-myelinated. Probably it is not wholly formed of afferent fibres, for these fine myelinated and non-myelinated fibres presumably belong to the autonomic nervous system and are efferent.—A. **Lipschütz**, B. **Ottow**, C. **Wagner**, and F. **Bormann**: The hypertrophy of the interstitial cells in the testicle of the guinea-pig under different experimental conditions. Partial castration often causes enormous hypertrophy of the interstitial tissue. This hypertrophy is not compensatory, for the tendency to

hypertrophy of interstitial cells is more marked in fragments with improved blood-supply. Hypertrophy appears to be independent of the internal secretory function of the testicle in its relation to the organism as a whole, and is a response to local conditions.

Linnean Society, February 2.—Dr. A. Smith Woodward, president, in the chair.—F. **Johansen**: The Canadian Arctic Expedition of 1913–18. The expedition started from Vancouver in the *Karluk* for Nome, in Alaska, where the equipment was procured. One party, under Mr. Stefansson, on the *Karluk* was caught in the ice in September, 1913, and carried westward until the vessel sank, in about 73° N. lat. and 160°–165° W. long. The party camped on an ice-floe, and the survivors reached Siberia in March, 1914, and Nome in May. Stefansson later organised a new search-party to proceed by sledge across Banks Land; he explored Parry Islands, discovering coal in Melville Island. Coasts hitherto unmapped were surveyed, and much geological and biological material was gathered, as well as many implements used by Esquimaux.—J. C. **Willis** and G. U. **Yule**: Some statistics of evolution and geographical distribution in plants and animals and their significance. The general result seems to show that evolution and geographical distribution have proceeded in a chiefly mechanical way, the effects of the various "other" factors that intervene—climatic, ecological, geological, etc.—being only to bring about deviations this way and that from the dominant plan. Every family and every genus, and in every country, behaves in the same way. Strong evidence is thus given for de Vries's theory of mutation and for Guppy's theory of differentiation (see NATURE, February 9, p. 177).—Mrs. E. M. **Reid**: Note on the hollow curve as shown by Pliocene floras. The material was that published from Tegelen, Castle Eden, etc. Fossil floras take their appropriate place alongside living floras, bringing direct evidence from the host to show the universality of the law of hollow-curve distribution.

Aristotelian Society, February 6.—Prof. Wildon Carr in the chair.—A. H. **Hannay**: Standards and principles in art. The problem of standards and objectivity in art is usually debated on the basis of standards and objectivity or no standards and subjectivity. Each new and individual work of art carries with it its own individual and original awareness. This view does not necessitate a lapse into subjectivism if it is realised that the awareness or taste is itself a striving for objectivity and rightness. The search for standards is the outcome of this incessant quest for right taste. Beauty is not entirely unique and indefinable. It is a process, a constructing, and can be differentiated from other processes such as history, science, and philosophy. Actually, modern criticism is full of psychological analyses which definitely involve reflective principles, but they are distinct from the old standards, for they do not pretend to anticipate the individual content of works of art. But do they precede, accompany, or follow upon æsthetic creation and appreciation? It is accepted that they are a later product, and this view has been stated very lucidly by Benedetto Croce. Yet history does not confirm it, and it does not explain the fact that criticism clarifies taste. It is suggested that the process imagination-principle is not a passage from one independent activity to another, but a development which requires both activities and in which a modification in one means a modification in the other. The critic emphasised the universal element, while the artist emphasised the individual element.

Zoological Society, February 7.—Dr. A. Smith Woodward, vice-president, in the chair.—C. W. **Hobley**: The fauna of East Africa and its future. Special attention was directed to the need for immediate action to preserve the herds of big game from total extinction.—Miss L. E. **Cheesman**: The position and function of the siphon in the amphibious mollusc *Ampullaria vermiformis*.—J. **Stephenson**: Contribution to the morphology, classification, and zoogeography of Indian Oligochæta. IV.: The diffuse production of sexual cells in a species of Chætogaster (fam. Naididæ). V.: *Drawida japonica*, Michlsn., a contribution to the anatomy of the Moniligastridæ. VI.: The relationships of the genera of Moniligastridæ, with some considerations on the origin of terrestrial Oligochæta.

Physical Society, February 10.—Dr. A. Russell, president, in the chair.—E. A. **Owen** and Bertha **Naylor**: The measurement of the radium content of sealed metal tubes. Tables have been compiled giving the corrections to be applied to the observed radium content of sealed platinum and silver tubes to obtain their true radium content. Two cases have been considered: (*a*) that in which the active deposit is uniformly distributed throughout the volume of the tube, and (*b*) that in which the active deposit is uniformly distributed over the inner wall of the tube. With constant wall-thickness the correction increases with the external diameter of the tube, and for the same increase of external diameter the increase of correction is more pronounced for the "empty" than for the full tube.—Sir William **Bragg**: The crystal structure of ice. The methods of X-ray analysis have been applied to ice by Ancel St. John and by D. M. Dennison. The former refers the structure to a lattice composed of right triangular prisms of side 4·74 Å.U. and height 6·65 Å.U.; the latter to a similar lattice of dimensions 4·52 Å.U. and 7·32 Å.U. respectively. The arrangement of the atoms was not found. On certain suppositions the arrangement can be found independently of direct X-ray analysis. Assume that each positive ion is surrounded symmetrically by negative ions, and *vice versa*; and, in view of the low density of ice, let the number of neighbours be in each case as small as possible. The crystal is to be hexagonal and to have the right density. Then each oxygen atom is at the centre of gravity of four neighbouring oxygens, from each of which it is separated by a hydrogen atom. The dimensions of the structure agree with Dennison's figures, and the calculated intensities of reflection agree well with the observed intensities recorded by Dennison.—Kerr **Grant**: A method of exciting vibrations in plates, membranes, etc., based on the Bernoulli principle. A plate placed close to a flanged orifice from which a stream of air or liquid is issuing is attracted towards the orifice. If the plate be mounted as a diaphragm it can be excited to strong vibration by a suitable blast, and a loud sound is produced with high efficiency.

Faraday Society, February 13.—Prof. A. W. Porter, president, in the chair.—J. R. **Partington**: The energy of gaseous molecules. The translational and rotational energies of gases are, at ordinary temperatures, approximately represented by the theory of equipartition, and any excess of C_v over 6 may be put down to internal motions. This excess is parallel to the activities of the gases. The translational energy may be represented on the quantum theory with a frequency equal to the collision frequency. The value of n in the equation $n=n_0(T/_{273})^n$, representing the effect of temperature on the viscosity, is related to the critical pressure (p_c in atm.) by the empirical equation $n=0{\cdot}642+0{\cdot}00116\,p_c+0{\cdot}0000399\,p_c^2$. The molecular heat of hydrogen may be represented empirically

by Debye's formula with a frequency $\nu = 6541/\sqrt{T}$. The molecular heat of nitrogen is very approximately given by a molecule based on Bohr's theory, with a frequency given by the gyrostatic formula.—U. R. **Evans**: Passivity and overpotential. (1) Where a metal is corroded by a liquid yielding an insoluble corrosion product, the latter may either cling to the metal, forming a thin protective covering (often invisible), or it may become dispersed in the solution; in the latter case it will not seriously interfere with corrosion. It is probably the relative values of the interfacial tension between the metal, corrosion-product, and solution that determines which will occur. (2) The activation of passive metals by chlorides is related to the known peptising action of metallic hydroxides by chlorides; the passivication by means of chromates is connected in part with the flocculating action of chromates. (3) The fact that metals with basic oxides are rendered active by acids and passive by alkalis, whilst those with acidic oxides tend to become passive in acids and active in alkalis, shows that the invisible protective layer is "of the nature of an oxide-film." But it seems wrong to identify it with any oxide known in the massive state; probably we have to deal with a layer of oxygen atoms connecting the metal on one side to the solution on the other. (4) Likewise, at a cathodically polarised electrode we probably have to deal with a layer of hydrogen nuclei connecting the metal to the liquid. The hydrogen is probably in a state intermediate between the elementary and the ionic, and by forming a link between metal and solution it serves to decrease the energy of the interface. Overpotential may be due to the energy needed to desorb the hydrogen.—A. W. **Porter**: Note on the vapour-pressure of ternary mixtures. The equation proposed for ternary mixtures in a previous paper is here applied to the case of mixtures of toluene, carbon tetrachloride, and ethylene bromide, and is found to be satisfactory.

Royal Meteorological Society, February 15.—Dr. C. Chree, president, in the chair.—C. E. P. **Brooks** and J. **Glasspoole**: The drought of 1921. The general rainfall in England and Wales was the least in 1921, so far as can be ascertained, since 1788. Individual long records indicated that over a considerable part of the south-east of England 1921 was the driest year for at least a century and a half. The months of 1921 were not individually so remarkable as was shown by a comparison with the driest months known to have occurred in the British Isles generally. As shown by a map of standard deviation of annual rainfall, 1881–1915, for the British Isles, the least fluctuations of annual rainfall occurred along the coast in the north-west, increasing to a maximum in the south-east and centre of the land masses. Constructing charts showing the distribution of barometric pressure over the globe during and preceding each of the great droughts, beginning with 1864, it is found that the conditions which commonly prevail during dry spells are high pressure over the British Isles, the greatest deviation from normal being usually over south-east England; low pressure over the Arctic regions, especially near Spitsbergen; and, generally, low pressure over the tropics. The first factor is related to the eleven-year sun-spot cycle, occurring most frequently two years after sun-spot minimum and three or four years after sun-spot maximum, so that it tends to recur every five or six years. Low pressure over the Arctic is related to ice conditions, and tends to recur every four or five years. Great droughts occur only when both these factors are favourable. With pressure low over the Arctic, two or three months' warning of a drought would be given by the development of high pressure over northern Russia.—T. **Kobayasi**: A cyclone which crossed the Korean Peninsula and the variations of its polar front The cyclone passed over a mountain range in Korea on March 25, 1918. It induced a secondary on the farther side of the range along the steering line, which extended upward until it joined with the primary; the secondary gradually grew stronger, and the original centre disappeared. The existence of the polar front was very distinctly marked, but complicated in character. There were two or more squall lines for one steering line.

EDINBURGH.

Royal Society, February 6.—Prof. F. O. Bower, president, in the chair.—J. M'Lean **Thompson**: The floral structure of *Napoleona imperialis*, Beauv. The flower structure of this curious African plant of the Myrtle family has remained a puzzle since the discovery of the plant in 1786. The flowers possess inside the corolla a series of petal-like growths, which it was held were produced during descent by transformation and replacement of cycles of stamens of a myrtle type of flower. These petaloid growths and the persisting cycle of stamens, which themselves are now partly sterile, are associated with a massy fleshy disc which surrounds the base of the style. The disc, stamens, and petaloid growths in question have now been shown from developmental study to have a common origin from a ring-like outgrowth which normally in the Myrtle family bears numerous groups of stamens, and were held to be the results of replacement of stamens during descent.—G. W. **Tyrrell**: The pre-Devonian basement complex of Central Spitsbergen. The rocks described constitute the basement which underlies the flat-lying Devonian and Carboniferous sediments in the region about the head of Klaas Billen Bay. They form the southern continuation of the extensive Wijde Bay region of Urgebirge, where these ancient rocks begin to be covered unconformably by a sedimentary mantle. Lithologically, they fall into a western zone of "Archæan" facies, consisting of quartz-schists, garnetiferous mica-schists, hornblende-schists and gneisses, lit-par-lit-gneisses, and augen-gneisses, with crystalline limestones; and an eastern zone consisting of slates, quartzites, and limestones similar to those of the Hecla Hoek system, the type-locality of which (Hecla Hoek, in Treurenberg Bay) lies exactly on the northern continuation of the line of strike of these rocks. Hence this group is believed to be of Hecla Hoek (probably Ordovician) age. The western schists and gneisses, while showing great similarities to rocks involved with the Hecla Hoek of the north-western mountains, may be much older, possibly even Archæan.

MANCHESTER.

Literary and Philosophical Society, November 1, 1921.—Mr. T. A. Coward, president, in the chair.—S. J. **Hickson**: Some early autographs of John Dalton. Variations in Dalton's handwriting were examined and attention was directed to certain family records.—R. W. **James**: The distribution of the electrons in atoms. When X-rays fall on an atom each electron of the atom probably becomes a source of scattered X-radiation; the waves scattered by the electrons in the direction of the incident light will be in phase, and the total amplitude scattered in this direction will be proportional to the number of scattering electrons. If the electrons in the atom lie at distances from the nucleus comparable with the wave-length of the X-rays, the waves scattered from the different

electrons in any direction making an angle with that of the incident radiation will not be in phase. Measurement of the intensity of the radiation scattered in different directions gives the diffraction pattern for the atom. The K_α doublet of rhodium falling on a crystal shows that each electron in the atom scatters independently. On the average, three or four electrons lie in the region near the edge of the atom, and the main concentration is much closer to the nucleus.

November 15.—Mr. R. L. Taylor, vice-president, in the chair.—S. **Chapman**: Certain integrals occurring in the kinetic theory of gases. In the kinetic theory of gases, if molecules are regarded as point-centres of force, the calculation of the intensity of the force from experimental determinations of gaseous viscosity depends upon numerical factors which have not hitherto been evaluated except in one case. The factors concerned have now been calculated in other cases.—J. E. **Jones**: The dynamics of collision of diatomic molecules. By the application of Maxwell's kinetic theory, a simple relation between the velocity with which the points of contact approach each other and the velocity with which they separate has been found; a simple relation between the impulse acting on each body at collision and the velocity of approach of the points of contact has been deduced and the impulse on collision calculated. The velocities after collision are then deduced from the ordinary dynamical equations of momentum.

Paris.

Academy of Sciences, February 6.—M. Emile Bertin in the chair.—L. **Lecornu**: Some remarks on relativity.—M. **Hamy**: The determination by interference of the diameters of stars the superficial brightness of which is not uniform.—C. **Richet**, E. **Bachrach**, and H. **Cardot**: The tolerance of the lactic ferment to poisons. It has been shown that the lactic acid organism gradually grows accustomed to poisons present in the culture media. It is now proved that this is specific, in the sense that a ferment grown tolerant to the presence of one poison still remains sensitive to another. The lactic ferment may be made to tolerate the presence of two different poisons simultaneously.—F. **Widal**, P. **Abrami**, and J. **Hutinel**: Researches on the proteopexic insufficiency of the liver in dysenteric hepatitis. The test previously described by the authors (enumeration of the white blood corpuscles after drinking a glass of milk, fasting) proves whether the liver is completely arresting incompletely disintegrated proteids, and this has proved to be a most sensitive test of the proper functioning of the liver. In dysentery the liver may be extensively attacked without affecting the proteopexic function.—M. **d'Ocagne**: The comparative examination of various nomographic methods.—A. **de Gramont** and G. A. **Hemsalech**: The evolution of the spectrum of magnesium under the influence of increasing electrical actions. Applications to astrophysics. From a detailed study of the effects of temperature and of the strength of the electric field on the lines of the magnesium spectrum various conclusions of interest in astrophysics are drawn. It is dangerous to conclude that a star possesses a high temperature because the spark-lines predominate in its spectrum. It is important to study the character of each line.—C. **Guichard**: Networks which are several times Ω_{00}.—J. **Timmermans**, Mlle. H. **Van der Horst**, and H. Kamerlingh **Onnes**: The melting points of pure organic liquids as thermometric standards for temperatures below 0° C. The temperatures were determined by a platinum resistance thermometer, standardised against the helium thermometer, of nine carefully purified liquids. The range covered is between −159·6° C. (isopentane) and −22·9° C. (carbon tetrachloride), with an error of less than 0·1° C. Specimens of these standard liquids will be distributed to other institutions later on.—M. **Gevrey**: Remarks on quasi-analytical functions.—G. **Julia**: Series of rational fractions and integration.—T. **Carleman**: A theorem of M. Denjoy.—G. **Sagnac**: The projection of the light of periodic double stars and the oscillations of the spectral lines.—D. **Coster**: The L series of the X-ray spectrum. The X-ray spectra of a large number of elements (from Ta to Rb) have been remeasured. In general, the new results confirm earlier work, and also give support to the theory of structure of the Bohr atom. Details are given in cases where the new measurements are not in agreement with the earlier observers.—M. **Bedeau**: Measurement of the dielectric constant of gases and vapours by means of circuits with sustained waves.—C. E. **Guye** and R. **Rüdy**: A new mode of determination of the molecular diameters by the electromagnetic rotation of the discharge in the gases. Earlier work had shown that whilst the molecular diameters obtained by this formula were of the same order of magnitude as those obtained by the viscosity method, the results were greatly influenced by the presence of traces of impurities. In the present work great care was taken in the purification of the gases, and comparative figures for the molecular diameters obtained by the electromagnetic rotation and the viscosity methods are tabulated for oxygen, nitrogen, carbon dioxide, hydrogen, nitrous oxide, methane, and carbon monoxide. The two sets are in fair agreement.—L. **Guillet** and J. **Cournot**: The variations of the mechanical properties of metals and alloys at low temperatures. Results are given for the resilience and Brinell test at 20° C., −20° C., −80° C., and −190° C. of electrolytic iron, steels, and alloys.—P. **Jolibois** and R. **Bossuet**: The relations between the different oxides of uranium. At 500° C. in a vacuum the oxide UO_3 loses oxygen, giving rise to U_3O_8, and the reaction is irreversible. The same oxide is formed by heating UO_2 in oxygen.—P. **Lebeau**: The oxides of uranium. The only oxides of uranium which have a certain existence are UO_3, U_3O_8, and UO_2. The green oxides prepared at temperatures below 800° C. contain variable quantities of uranic anhydride, and change in composition in contact with moist air.—H. **Pélabon**: The action of selenium on gold. Gold is slightly attacked by selenium; the metal fixes a little selenium, and the selenium itself takes up a little gold.—E. **Grandmougin**: Some new derivatives of sulphobenzide.—G. **Dupont**: The composition of Aleppo essence of turpentine. This turpentine contains 95 per cent. of pinene, 1·14 per cent. of inactive bornyl acetate, and 3·8 per cent. of sesquiterpene.—G. **Mouret**: The eastern limit of the granitic massif of Millevaches.—P. **Glangeaud**: The Saint-Flour Oligocene basin. The Miocene Truyère flowing into the Allier.—P. **Négris**: Glacial phases in Greece.—R. **Bourret**: The strata in the north-east of Tonkin.—L. **Dussault**: The geology of western Tonkin.—E. **Saillard**: Composition of the wild beetroots.—R. **Stumper**: New observations on the poison of ants. The concentration of the formic acid in *Formica rufa* was found to vary between 21 and 73 per cent. of pure acid. Formic acid is always present in the Camponotinæ, but absent in Myrmicinæ and Dolichoderinæ.—M. **Doyon**: The incoagulability of the circulating blood provoked in the frog by injections of nucleic acids. Duration of the phase. Comparison with various anti-coagulants.—A. A. **Mendes-Corrêa**: The asymmetry of the skeleton of the upper

limbs.—MM. **Alezais** and **Peyron**: The histogenesis and origin of the chordomes.—E. **Burnet**: A new method of diagnosis of Mediterranean fever. The test proposed is the intradermal reaction produced by a drop of a broth-culture of *Micrococcus melitensis*.—M. **Léger** and A. **Baury**: The shrew, *Crocidura Stampflii*, and the plague in Senegal. This animal has been proved to carry plague, and also fleas. Its destruction should be carried out systematically along with the rat.

Official Publications Received.

Agricultural Research Institute, Pusa. Bulletin No. 123, 1921: The Bundelkhand Cottons: Experiment in their Improvement by Pure Line Selection. By B. C. Burt and Nizamuddin Hyder. Pp. iv +15. (Calcutta: Government Printing Office, 1921.) 4 annas.

Memoirs of the Department of Agriculture in India. Entomological Series, Vol. 7, No. 6: Life-Histories of Indian Insects. Diptera: *Sphyracephala Hearseiana*, Westw. By S. K. Sen. Pp. ii +33-38+plates 4 and 5. (Pusa: Agricultural Research Institute.) 12 annas; 1*s*.

Diary of Societies.

THURSDAY, FEBRUARY 23.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. A. G. Perkin: Dyeing: Ancient and Modern (2).

INSTITUTION OF ELECTRICAL ENGINEERS, at 3.30 and 8.—Meeting in Commemoration of the First Meeting of the Society of Telegraph Engineers on February 28, 1872.

ROYAL SOCIETY, at 4.30.—C. D. Ellis: β-ray Spectra and their Meaning.—Prof. A. E. Conrady: A Study of the Balance.—Dr. J. S. Owens: Suspended Impurity in the Air.—R. V. Southwell: The Free Transverse Vibrations of a Uniform Circular Disc clamped at its Centre, and the Effects of Rotation.—A. E. Oxley: Magnetism and Atomic Structure. II. The Constitution of the Hydrogen-palladium System and other similar Systems.—T. Carleman and Prof. G. H Hardy: Fourier's Series and Analytic Functions.—Prof. A. McAulay: Multenions and Differential Invariants. II. and III.

ROYAL SOCIETY OF MEDICINE (Balneology and Climatology Section), at 4.30.—Dr R. L. J. Llewellyn and others: Discussion on The Etiology of Gout.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute, 90 Buckingham Palace Road, S.W.1), at 6.—A. E. Hayes: Phonoscript.

INSTITUTION OF AERONAUTICAL ENGINEERS (at Royal Society of Arts), at 7.30.—Lt.-Col. Moore-Brabazon: The Early Days of Aviation (Presidential Address).

CONCRETE INSTITUTE, at 7.30.—H. K. Dyson: What is the Use of the Modular Ratio?

ROYAL SOCIETY OF MEDICINE (Urology Section), at 8.30.—Prof. P. J. Cammidge: The Source of the Amylolytic Ferment of the Urine. —Dr. G. A. Harrison: Glycosuria in Renal Disorders.

FRIDAY, FEBRUARY 24.

ASSOCIATION OF ECONOMIC BIOLOGISTS (in Botanical Lecture Theatre, Imperial College of Science and Technology), at 2.30.—Dr. J. Rennie: (*a*) The Present Position of Bee Disease Research; (*b*) Demonstration of Polyhedral Disease in Tipula Species.

ROYAL SOCIETY OF ARTS (Joint Meeting of the Dominions and Colonies and Indian Sections), at 4.30.—Prof. W. A. Bone: Brown Coals and Lignites: Their Importance to the Empire.

ROYAL SOCIETY OF MEDICINE (Study of Disease in Children Section), at 5.—Dr. C. P. Lapage and Dr. W. J. S. Bythell: Tonic and Atonic Hearts in Children (with Radiographic Illustrations).

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.—Dr. H. Levy: The Number of Radio-active Transformations as Determined by Analysis of the Observations.—Prof. C. H. Lees: A Graphical Method of Treating Fresnel's Formulæ for Reflection in Transparent Media.—Research Department of the General Electric Co., Hammersmith: Demonstrations of a Rapid Weighing Balance, and an Electrostatic Voltmeter.—F. C. Dyche-Teague: Demonstration of the Physical Properties of Cellactite.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—H. Main: A Pilgrimage to Provence.

INSTITUTION OF PRODUCTION ENGINEERS (at Institution of Mechanical Engineers), at 7.30.—G. W. Eastwood: Intensive Production of Automobile Bodies.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—Prof. E. G. Coker: Curved Beams, Rings, and Chain Links.

ROYAL SOCIETY OF MEDICINE (Epidemiology and State Medicine Section), at 8.—Dr. Evelyn D. Brown: The Relation between Puerperal Septicæmia and other Infectious Diseases, with Reference to the Admission of Maternity Cases into Isolation Hospitals.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. J. Joly: The Age of the Earth.

SATURDAY, FEBRUARY 25.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. E. A. Gardner: Masterpieces of Greek Sculpture (2).

MONDAY, FEBRUARY 27.

INSTITUTE OF ACTUARIES, at 5.—C. H. Maltby: Results of an Investigation into the Effects of Different Valuation Bases upon Surplus.

INSTITUTION OF MECHANICAL ENGINEERS (Graduates' Association Meeting), at 7.—Sir Henry Fowler: Metallurgy in Relation to Mechanical Engineering.

ROYAL SOCIETY OF ARTS, at 8.—Prof. A. F. C. Pollard: The Mechanical Design of Scientific Instruments (Cantor Lecture) (2).

ROYAL SOCIETY OF MEDICINE (Odontology Section), at 8.—Clinical Evening.

MEDICAL SOCIETY OF LONDON (at 11 Chandos Street, W.1), at 8.30.—G. G. Turner, Sir Lenthal Cheatle, W. H. Clayton-Greene, W. James, and W. G. Howarth: Discussion on The Treatment of Tuberculous Glands.

TUESDAY, FEBRUARY 28.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Arthur Keith: Anthropology of the British Empire: Series 1: Racial Problems in Asia and Australasia (2).

ROYAL SOCIETY OF MEDICINE (Medicine Section), at 5.30.—Dr. E. I. Spriggs and O. A. Marxer: A Review of Sixty-one Cases seeking Relief after Short-circuiting Operations.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—T. Bell: Present-day Portraiture.

ILLUMINATING ENGINEERING SOCIETY (at Royal Society of Arts), at 8.—L. Gaster and others: Discussion on Industrial Lighting: Ideal Requirements (legislative and otherwise) and Practical Solutions.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Miss R. M. Fleming: Sex and Growth Features in Racial Analysis.

INSTITUTION OF AUTOMOBILE ENGINEERS (Informal Meeting) (at Institution of Mechanical Engineers), at 8.30.—Demonstration of, and Discussion on, Various Recording Instruments used on Motor Cars.

WEDNESDAY, MARCH 1.

NEWCOMEN SOCIETY (at Caxton Hall, Westminster), at 5.—R. Young: Timothy Hackworth and the Locomotive.

ROYAL SOCIETY OF MEDICINE (Surgery Section), at 5.30.—Informal Discussion on The Treatment of the Acute Obstruction resulting from Carcinoma of the Colon.

INSTITUTION OF ELECTRICAL ENGINEERS (Wireless Section), at 6.—E. B. Moullin and L. B. Turner: The Thermionic Triode as Rectifier.

ROYAL SOCIETY OF ARTS, at 8.—E. Moor: The Duplex-coupler Pianoforte.

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at Chemical Society), at 8.—R. V. Wadsworth: The Theobromine Content of Cacao Beans and Cocoa.—A. H. Bennett and F. K. Donovan: The Determination of Aldehydes and Ketones by Means of Hydroxylamine.—R. E. Essery: The Value of Fish Scales as a Means of Identification of the Fish Used in Manufactured Products.—N. Evers and G. D. Elsdon: The Examination of B.P. Ointments.

THURSDAY, MARCH 2.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. H. M. Lefroy: The Menace of the Insect Pest: The Balance of Life in Relation to Insect Pest Control (1).

ROYAL SOCIETY, at 4.30.—*Probable Papers*.—Prof. L. N. G. Filon and H. T. Jessop: The Stress-optical Effect in Transparent Solids strained beyond the Elastic Limit.—W. E. Curtis: The Structure of the Band Spectrum of Helium.—S. Datta: The Spectrum of Beryllium Fluoride.—W. G. Palmer: The Catalytic Activity of

Copper. Part III.—Dr. G. B. Jeffery: The Motion of Ellipsoidal Particles immersed in a Viscous Fluid.—Dr. G. B. Jeffery: The Rotation of Two Circular Cylinders in a Viscous Fluid.
LINNEAN SOCIETY OF LONDON, at 5.—R. E. Holttum: The Flora of Greenland.—J. Walton: The Ecology of the Flora of Spitzbergen. —Sir W. A. Herdman: "Spolia Runiana," V.
ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.30.—W. D. Douglas: Testing Aircraft to Destruction.
INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—Discussion on Starters: Introductory Papers by C. H. Wordingham: The B.E.S.A. Specifications for Starters.—J. Anderson: Electric Motor Starters.—W. Wilson: Some Notes on the Design of Liquid Rheostats.
CHEMICAL SOCIETY, at 8.
ROYAL SOCIETY OF MEDICINE (Obstetrics and Gynæcology Section), at 8.—G. Luker: A Wandering Silk Suture Removed from the Urethra as a Sequel to Cæsarean Section.—Dr. C. D. Lochrane: Decidual Reaction in Adenomyoma of Vaginal Wall.—Dr. R. A. Gibbons: Sterility with Reference to the State.

FRIDAY, MARCH 3.

ROYAL SOCIETY OF MEDICINE (Laryngology Section), at 4.45.—E. M. Woodman, Dr. Reginald Morton, and others: Discussion on The Treatment of Malignant Growths of the Nasal Accessory Sinuses.
ROYAL ASTRONOMICAL SOCIETY, at 5.—Geophysical Discussion on The Depth of Earthquake Foci. Chairman: Sir Frank Dyson. Speakers: Prof. H. H. Turner, Dr. J. W. Evans, Dr. Dorothy Wrinch, Dr. H. Jeffreys.
INSTITUTION OF MECHANICAL ENGINEERS (Informal Meeting), at 7.—A. P. Bale: Spiral Bevel *v.* Straight-tooth Bevel.
JUNIOR INSTITUTION OF ENGINEERS, at 8.—E. T. Elbourne: Factory Administration.
ROYAL SOCIETY OF MEDICINE (Anæsthetics Section) (Annual General Meeting), at 8.30.—Dr. Z. Mennell: Anæsthesia in Intracranial Surgery.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Dr. C. M. Wenyon: Microscopic Parasites and their Carriers.

SATURDAY, MARCH 4.

INSTITUTION OF LOCOMOTIVE ENGINEERS (at Caxton Hall, S.W.1), at 2.15.—J. Clayton: Lubrication of the Modern Locomotive.
ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: Radio-activity (1).

PUBLIC LECTURES.

(*A number in brackets indicates the number of a lecture in a series.*)

THURSDAY, FEBRUARY 23.

INFANTS' HOSPITAL (Vincent Square, S.W.1), at 4.—Dr. W. M. Feldman: The Physiology and Pathology of the New Born; Initial Loss of Weight: Icterus Neonatorum.
UNIVERSITY COLLEGE, at 5.15.—Prof. J. E. G. de Montmorency: Welsh and Irish Tribal Customs (3).
KING'S COLLEGE, at 5.30.—Dr. O. Faber: Reinforced Concrete (6).
ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN (Leicester Square, W.C.2), at 6.—Dr. W. Griffith: The Bullous Eruptions (Chesterfield Lecture).
BIRKBECK COLLEGE, at 8.—G. Bernard Shaw: The Failure of Education.

FRIDAY, FEBRUARY 24.

METEOROLOGICAL OFFICE (South Kensington), at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (6).
CANCER HOSPITAL (Fulham Road, S.W.3), at 4.—W. E. Miles: Cancer of the Rectum.
UNIVERSITY COLLEGE, at 5.—Prof. G. Elliot Smith: The Evolution of Man (3).
TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES (at Mary Ward Settlement, Tavistock Place, W.C.1), at 5.30.—Dr. H. Crichton Miller: The New Psychology and its Bearing on Education (5).

SATURDAY, FEBRUARY 25.

LONDON DAY TRAINING COLLEGE, at 11 a.m.—Prof. J. Adams: The School Class (6).
HORNIMAN MUSEUM (Forest Hill), at 3.30.—Dr. W. A. Cunnington: Man's Sphere in Savage Africa.

MONDAY, FEBRUARY 27.

CITY OF LONDON (BOYS') SCHOOL (Victoria Embankment), at 5.30.—Miss Rosa Bassett: The Dalton Plan of Self-education (4).

TUESDAY, FEBRUARY 28.

IMPERIAL COLLEGE—ROYAL SCHOOL OF MINES, at 5.30.—Col. N. T Belaiew: The Crystallisation of Metals (2).
LONDON SCHOOL OF ECONOMICS AND POLITICAL SCIENCE, at 6.—Sir Josiah Stamp: The Administrative Factor in Government (3).

WEDNESDAY, MARCH 1.

EAST LONDON COLLEGE, at 4.—Prof. F. E. Fritch: Certain Aspects of Freshwater Algal Biology (3).
LONDON (R.F.H.) SCHOOL OF MEDICINE FOR WOMEN, at 5.—Dr. H. H. Dale: Some Recent Developments in Pharmacology (2).
HORNIMAN MUSEUM (Forest Hill), at 6.—W. W. Skeat: The Living Past in Britain (6).
UNIVERSITY COLLEGE, at 8.—The Current Work of the Biometric and Eugenics Laboratories (3).—Dr. P. Stocks: Scheme of Anthropometric Measurements in the Biometric Laboratory.

THURSDAY, MARCH 2.

INFANTS' HOSPITAL (Vincent Square, S.W.1), at 4.—Dr. W. M. Feldman: The Physiology of the Infant (1).
SCHOOL OF ORIENTAL STUDIES, at 5.—Dr. L. D. Barnett: The Hindu Culture of India (1).
UNIVERSITY COLLEGE, at 5.15.—Prof. J. E. G. de Montmorency: Welsh and Irish Tribal Customs (4). At 5.30.—Dr. C. Pellizzi: Giardano Bruno in Inghilterra (In Italian).
KING'S COLLEGE, at 5.30.—Dr. O. Faber: Reinforced Concrete (7).
ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN (Leicester Square, W.C.2), at 6.—Dr. W. Griffith: The Treatment of Skin Diseases (Chesterfield Lecture).
CIVIC EDUCATION LEAGUE (at Leplay House, 65 Belgrave Road, S.W.1), at 8.15.—Miss Margaret Tatton and others: Discussion on Art in Relation to Education.

FRIDAY, MARCH 3.

METEOROLOGICAL OFFICE (South Kensington), at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (7).
UNIVERSITY COLLEGE, at 5.—Prof. G. Elliot Smith: The Evolution of Man (4).
TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES (at Mary Ward Settlement, Tavistock Place, W.C.1), at 5.30.—Dr. H. Crichton Miller: The New Psychology and its Bearing on Education (6).

SATURDAY, MARCH 4.

POLYTECHNIC (Regent Street, W.1), at 10.30 a.m.—Prof. A. Harden: Vitamins.
LONDON DAY TRAINING COLLEGE, at 11 a.m.—Prof. J. Adams: The School Class (7).
HORNIMAN MUSEUM (Forest Hill), at 3.30.—F. Balfour-Browne: Dragon-flies and their Life-history.

Cycles in the Yield of Crops.

NEARLY five-and-twenty years have elapsed since Sir Arthur Schuster, by devising the orderly and comparatively brief process known as the "periodogram method," gave a great stimulus to the investigation of periodicities in natural phenomena. Solar and magnetic phenomena provided the first fields of application, and meteorological data have since been attacked by many investigators. It seems fitting that crops, which are so largely dependent on the weather, should be submitted to the same test.

In the course of last year Prof. H. L. Moore, of Columbia University, published a series of three articles in the American *Quarterly Journal of Economics*, which may be briefly summarised as indicating that, in the periodogram for periods of three to twelve years, there is a marked maximum at eight years in the cycles of a number of crops and corresponding cycles in the production of the raw materials of industry. This periodicity appears to correspond to what is known as the "economic cycle" in trade, and it is suggested that the periodicity in crops is the *generating cycle* of the whole movement—a movement which is very clearly reflected in prices. Prof. Moore's data refer, for the most part, to the years 1882–1918 only, with the exception of Sauerbeck's data for prices in this country, which are available from 1818, and of wheat prices in England, which are utilised for the years 1870–1916. To the latter part of his third article we return briefly below.

In the meantime, in an article published in the British *Economic Journal* for March 1920, Sir William Beveridge suggested, on evidence which, to many readers, did not seem at all adequate, the existence of a period "between 15·2 and 15·4 years." In the same journal for December 1921, a further paper was published in which the original conclusion is completely vindicated. By the aid of overlapping data as to wheat prices in a large number of places in Great Britain, France, Germany, and the Netherlands, an index-number of wheat prices for Western Europe is constructed running from 1500 to 1869. The index-number for each year is then expressed as a percentage of the mean of the thirty-one years surrounding it, and the results are submitted to periodogram analysis over the three centuries 1545–1844, for periods running from two years to thirty-six. Data are also given separately for 1545–1694 and 1695–1844.

For the whole 300 years and for the last 150 years the greatest intensity, taking only integral periods, is at fifteen years, the maximum being well marked; for the earlier 150 years the intensity at 15 (70) is slightly exceeded by the intensity at 11 (76), 13 (80), and 18 (73). Testing fractional periods on the series as a whole, the intensity at 15 (47) is raised to 82 at 15⅓, and to 80 at 15½. The dominant period appears, therefore, to be fairly closely 15·3.

But, Sir William Beveridge suggests in an interesting analysis that follows, the period thus found is probably not a real one—*i.e.* is not the period that exists in the operative cause, the weather. If a certain cycle exists in the weather tending to give, say, abnormally heavy rain at its maximum, it will nevertheless not have any adverse influence on the harvest unless the maximum and its accompanying deluge fall within the limited period of year during which the crop is growing. Hence what will be observed in the crop is not necessarily the period of the weather cycle, but the period in which its maximum tends to recur during the critical months. We have not space to follow the author's reasoning in detail, but it is suggested that there are at least two weather cycles operating, if not four—(*a*) with a period of approximately 4·37 years (30·6/7), which corresponds to a cycle identified by Sir Arthur Schuster in sunspots; (*b*) with a period of about 5·11 years (30·6/6), which has been found in temperature and rainfall records; and two of less certainty, (*c*) with a period of 2·74 years (30·6/11), and (*d*) with a period of 3·71 years, both of which also appear to have been identified in meteorological or astronomical data.

The period observed, it is argued, arises from a temporary compounding of the effects of these four cycles. All four "are due to return to a maximum phase between February and September 1923," and this may mean an exceptionally bad year for harvests in Europe. "In the excessively improbable event of my arithmetical analysis being complete and accurate in every particular," Sir William Beveridge continues

"1923 is destined to repeat something like the experiences of 1315, the year of the worst and most general harvest failure known in European history." To the crowd, if not to the man of science, the fulfilment of a prophecy always seems to give more adequate support to a theory than any number of agreements with past events, and the year 1923 may be awaited with an interest mingled with anxiety. On the face of it, the evidence seems sound, and the reasoning careful and critical.

Sir William Beveridge does not attempt to trace the physical causation of the observed periodicity further than to show that it may be accounted for by cycles already noted in meteorological or astronomical data. The eight-year period gives only a small maximum in his periodogram with an intensity of 12. Years after 1844 were apparently omitted in part because during the nineteenth century the character of the curve visibly alters, the "credit cycle" acting as a "disturbing influence." It may, however, be questioned, in view of Prof. Moore's work, whether the credit cycle can be treated in this way as an extraneous disturbing cause. An eight-year cycle, as he says, was isolated in the barometric pressure of the United States, and has also been traced in rainfall, and these cycles appear to be congruent with the economic cycle. When Prof. Moore goes beyond this and seeks for a cosmic cycle that may be regarded as the "generating cycle," he lights on an hypothesis for which, we think, a good deal of further evidence will be required before it can win acceptance; it is suggested that the period in question is that between conjunctions of the earth and Venus. No proof, however, is given that the periods coincide with any precision, the periodograms for economic data having been calculated only for integral periods.

Analysis must be carried further before a true consonance of the periods can be predicted with any confidence. The point brought out by Sir William Beveridge, moreover, that the period in the weather may not be that in the yield of the crop, must be borne in mind. If a "maximum" of some kind in the weather is vital to the crop only provided that it occur at some critical period of the year, the determination of this critical period becomes of interest, and we would suggest that such work as that of Mr. R. H. Hooker, of the Ministry of Agriculture, whose presidential address to the Royal Meteorological Society on the correlation in eastern England between yield and the weather in successive months of the year was summarised on p. 193 of NATURE for February 9, might help to elucidate the matter. Crop prediction is a matter of the highest economic importance, and all lines of investigation should be considered together.

A Searchlight on Solids.

Aggregation and Flow of Solids: Being the Records of an Experimental Study of the Micro-structure and Physical Properties of Solids in Various States of Aggregation, 1900–1921. By Sir George Beilby. Pp. xv+256+34 plates. (London: Macmillan and Co., Ltd., 1921.) 20*s*. net.

THIS is a book that will hold a true child of science like any fairy-tale, and it would be difficult to overstate its fascinating interest. In form, in substance, and in all its auspices it is so highly individual. It is a story, a connected story, of the leisure pursuits of one of our leading and most enlightened industrialists, who for many years, and pre-eminently in the stress of war, has rendered great

FIG. 1.—Globules of zinc dust picked up on the edges of a thin steel blade (×60). From "Aggregation and Flow of Solids."

services to his country. But it is a record that would adorn a life wholly devoted to the pursuit of science.

All who are seriously concerned with physical or chemical science must know something of the contributions which Sir George Beilby has made to the subject dealt with in this book, but the rush of scientific discovery makes it very difficult to realise the full sweep and significance of much that is going forward. Probably every one knows that Sir George Beilby has demonstrated the existence of a vitreous state in metals and other solids where that state had never been suspected, and to most of us he has become permanently "featured" on the transparent *surface film* of polished solids.

In his papers from time to time he has disclosed in some degree the theoretical accompaniment and the connecting threads of his experimental work, but it is probable that few will have seen the extraordinary breadth and comprehensiveness of the ideas which have developed as the work proceeded, or have realised

the extent of their implication in matters of great scientific and practical importance.

The work under notice now tells the whole tale in a form which leaves nothing to be desired, and adds at least one new chapter. It is not difficult to understand how much it must have cost of resolution and hard labour to bring to its present form the vast amount of material that had accumulated in Sir George Beilby's hands, and we must all be grateful to Sir Herbert Jackson, whose persuasiveness brought Sir George Beilby to the point of setting out on his task, and whose help, along with that of Mr. W. D. Haigh, is very gratefully acknowledged by the author. "I unhesitatingly say," he states, "that without his (Mr. Haigh's) constructive skill and insight the work would not have been accomplished." And we may add that no one more than Sir Herbert Jackson was in a position to appreciate the importance of Sir George Beilby's work.

FIG. 2.—Crystalline antimony polished by emery and rouge and etched with potassium cyanide, showing film of flowed metal covering pits. From "Aggregation and Flow of Solids."

The letterpress extends over some 250 pages, clearly printed and in every respect easily readable. The concluding part consists of thirty-four beautiful reproductions of a series of figures, nearly all photographic. Not one of them is uninteresting, and most of them are remarkable. In the letterpress the topics dealt with in sequence are the following: Microscopic methods and measurements; surface tension films in liquids and solids; the varied ways in which aggregation takes place; cohesion among minute solid particles and between these particles and flat surfaces; polish, the result of surface flow; the crystalline and vitreous states in solids; influence of the crystalline and vitreous states on the physical and mechanical properties of ductile metals; influence of the crystalline, mobile, and vitreous states on the flow of rocks and ice; molecular pulsation cells: a tentative hypothesis; extension of Faraday's work on the optical and other characteristics of thin metal leaves; phosphorescence of crystals effected by the change from the crystalline to the vitreous state.

The general nature of Sir George Beilby's work can probably be best understood by thinking of the conditions under which it was carried out. We have to picture a man of scientific taste and talent, whose lot has been cast in the industrial world, eager to devote his leisure to the advancement of fundamental knowledge and compelled to select a topic that can be cultivated experimentally under home conditions, that do not give any very exceptional facilities for experimental work. Under these limits, what better than to take up the study of some topic of micro-chemistry or micro-physical chemistry? Able to provide himself with the best appliances for his purpose, and skilled in the manipulative art of the chemist, he develops a highly special technique, and with all these resources applies himself to particular problems of his subject. The result is a series of refined observations and delicate manipulations which has disclosed many things never seen before and established many new facts about the structure and behaviour of solids.

It is really very difficult to give a summary of what is contained in this book. It would be rather like writing a short paragraph summarising the incidents of an Antarctic explorer's voyage of discovery. No doubt it is possible to say, in a word, that the centre of Sir George Beilby's doctrine is the vitreous film of solids, but the great interest of the book lies in the record of successive experimental steps by which the facts have been established and amplified. To the student of molecular physics, the metallurgist and engineer, the geologist, the fine artificers of glass and metal, the records have something of first-rate importance to say.

The present writer is probably not singular in having felt surprise on first learning that the final perfect polish of glass or metal was produced by the use of an abrading agent. One could understand the finer and finer scratches of grinding giving a greater and greater smoothness, and it was possible in the

mind to conceive the *ad infinitum* refining of scratches to the attainment of a perfect sheen. But in actual practice, with a last abrasive even so fine as particles of rouge, it seemed as if there must somehow be a jump at the end between these earthy scratches and the perfect polish of speculum or plate glass. The practical attainment of such a polish seemed much

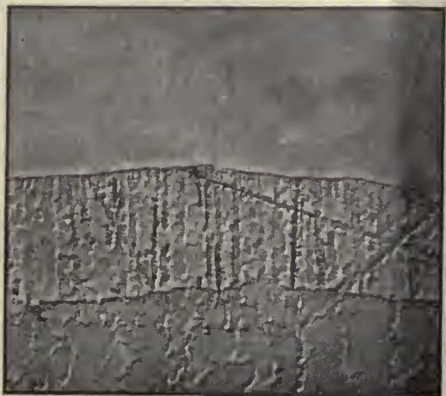

FIG. 3.—Etched calcite surface showing the untouched skin and the under surface at 500 and 1000 $\mu\mu$. From "Aggregation and Flow of Solids."

more easily understood when a custodian of some of the finest old silver at Cambridge, on being asked how the brilliance was produced, simply exhibited the flesh side of an ample thumb, with a gesture and mien indicative of a *flattening* pressure exerted steadily through the ages. Sir George Beilby now tells us, and it is a relief to know it, that the microscopically differentiable particles of rouge are smaller than we thought, that they are also much harder, and that when they are spread over a leather they present a layer such that when the leather is passed over the glass or metal surface, this is *seized* as a whole, the mobility of a liquid is temporarily produced, and when the leather has passed, a film is left with all the qualities of matter that has set like melted glass. Not only so, but "whilst to produce 'mass flow' in the hardened steel of which a razor is made a differential pressure of hundreds of tons per square inch would be required, yet the 'surface flow' necessary to keep the edge of the razor in perfect cutting condition can be effected by lightly stropping the blade on the bare hand a few times daily, before and after use!"

These examples are perhaps sufficient to indicate why and how this work on the surface leads to a study of the hard and soft state in metals, the flow of rocks and ice, the phosphorescence and triboluminescence of solids, and many other things besides.

A word must be said about the magnitudes dealt with in the investigations. The study of a calcite surface will suffice as an illustration :—

"When a condensed beam of sunlight was used to give oblique illumination of the surface, it was possible to detect the effect of a drop of acid which contained only 0·000125 per cent of HCl. The depth of the layer removed did not exceed 0·62 $\mu\mu$. . . . If it is correct to assume that the solvent effect of the acid was uniformly distributed over the whole surface of the pit, then it follows that a roughening of the surface not more than two molecules in depth has been detected." Again, "the mechanical disturbance caused [on calcite] by the polishing agent penetrates to a depth of 500 to 1000 $\mu\mu$."

The frame of reference of Sir George Beilby's thinking has been almost wholly that which preceded subatomism. In a short chapter he sketches his tentative working hypothesis of molecular "pulsation cells." Of this it must suffice to say that it has clearly served its purpose, for it has worked—it has led to a solid output of new knowledge. "Cohesion" is isolated in the old way as a force *sui generis*, and a fine picture is made of cohesion holding matter together in a dead world until there comes the advent of heat "like the first breath of approaching spring into the sleeping buds." Sir George Beilby has brought his rich gift of facts up to the frontiers of the newer physical

FIG. 4.—Microscopic crystal of antimony. From "Aggregation and Flow of Solids."

science. It must obviously engage the interest of those on the other side. There are especially to be mentioned the Braggs, the work and views of Langmuir, and the new light on lubrication coming from W. B. Hardy's experiments. But whatever may be added, the facts remain as a remarkable addition to scientific knowledge.

In conclusion, one or two suggestions may be made.

As to faults, there is need of revision at the beginning of the book in reference to the characteristic of the boiling-point. There is no index, and though one can see the peculiar difficulty of indexing this book, the omission is an inconvenience. It seems worth considering whether enlarged copies of the beautiful photographs which illustrate the book might not be issued so that they could be framed and hung on class-room walls.

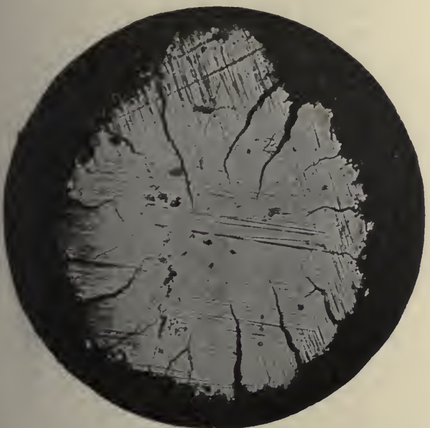

FIG. 5.—The crystal of Fig. 4 flattened by a single blow from a small drop-hammer; the thin plate was in a highly strained condition and the cracks developed in 24 hours. From "Aggregation and Flow of Solids."

A last suggestion, offered to teachers, is that this book should be freely prescribed to students of physical science. It seems very important in times with so strong an atmosphere of relativity and with *quanta* to some of us almost more than *suff.*, that students should see how much may still be accomplished by a faithful, indefatigable experimenter, who, with full knowledge, yet without prejudice, will scrupulously examine what lies positively and immediately in front of him.

A. SMITHELLS.

Pictish Stone Circles.

On Some Antiquities in the Neighbourhood of Dunecht House, Aberdeenshire. By the Rt. Rev. Dr. G. F. Browne. Pp. xiv+170+63 plates. (Cambridge: At the University Press, 1921.) 63*s.* net.

DUNECHT HOUSE, Aberdeenshire, became known to science by the researches of Drs. Copeland and Lohse at an observatory established there by the Earl of Crawford. The district so thoroughly examined by the distinguished author of this superb book is that of Lady Cowdray's Scottish estate and the immediate surroundings, a district known as "'twixt Don and Dee."

Confining my remarks to the subject which is given the largest space in the book, there is in the district of Dunecht a "large number of stone circles unique in type" (p. 1), the characteristic feature being a tangential alignment, generally in the south-west quadrant, made by a recumbent stone and its upright flankers. Of these circles Sir Norman Lockyer examined twenty-nine, and in fifteen instances he found a clock-star alignment at right angles to the recumbent stone. He discovered, in fact, the key to this unique type of circle. In my opinion, the glory of Dr. Browne's work on the Dunecht circles shines in the fact that in it the typical Pictish temple thrown open by Sir Norman Lockyer may now be inspected to the smallest detail.

A happy inspiration led the author to appeal to the Principal of the University of Aberdeen for a survey to be made of three circles, using the recumbent stone and flankers as a tangential base line, and measuring the alignment made by each stone with the middle of the recumbent stone. The survey was made by Drs. Fyvie and Geddes, and the circles were those of Midmar, Castle Fraser, and Sin Hinny (Sunhoney). It is most fitting that the three plans form Plate I.

Realising the importance of Dr. Browne's contribution to science, I have examined the seven plans of circles given in the book, and find that the alignments of the other four are also to be interpreted from the recumbent stone, the evidence being alignments in pairs at right angles to each other.

The whole truth, partly discovered by Sir Norman Lockyer, seems to be this: In the Pictish type of circle all alignments must have been originally made in pairs at right angles to each other. Finding this first, or fundamental, principle of circle-building fully established in each of the seven cases examined, I have applied that principle to test the present condition of each circle. By such a test six circles are found to be defective, and I think it is quite possible, theoretically, to restore the defective parts.

It is most fortunate that one circle is perfect according to the revealed Pictish standard, and that is Auchquhorthies (p. 69). It consists of a recumbent stone and flankers and nine other stones (the three stones on the inner side of the recumbent stone had probably some supplementary use). The outer sides of the flankers are aligned with the recumbent stone, but on their inner sides they have separate alignments which rank in the rectangular scheme of the circle and, with those of the nine out-lying stones, have a common base at the middle of the recumbent stone. The twelve separate alignments made by the twelve stones of the circle proper present six pairs of complementary measures. To obtain this result it is necessary

to measure the angular width of each stone from the observational base, and both the side measures and the average measures thus obtained should be studied. The following are averaged measures :—

1.	N.W. 72° S.E. (base line) . .	N. 19° E.
2.	East point	N. 2° E.
3.	N. 74° E.	N. 13° W.
4.	N. 63° 15′ E.	N. 28° W.
5.	N. 48° 45′ E.	N. 42° W.
6.	N. 33° 45′ E.	N. 57° W.

The average angle for the series is about 89° 30′. In two instances, side alignments form perfect right angles. In other instances it seems highly probable that the angular width of a stone was utilised for two alignments. Thus, of the side measures averaged as N. 42° W., the one on the north side of the stone is 38° and the one on the south side is 46°. By the table of solstitial azimuths for lat. 57° N. given on page 381 of "Stonehenge" (sec. ed.), 46° would be sunset at the summer solstice with a horizon of 2° high, and 38° would be sunrise at the winter solstice with the horizon a trifle higher.

It is a great thing to know that the position of each stone in a Pictish circle is, or was intended to be, at right angles to some other position. If the observational base of other types of circles could be discovered it is extremely likely that the same fundamental principle would be found applied. Given a number of rectangular alignments, with horizon measures, it is practically certain that for each circle a star cast, like that of actors in a drama, could be made out, making the determination of the period involved comparatively easy.

Without horizon measures, the solar alignments of the Dunecht circles are easily recognisable. Judging by the one complete circle described, we are warranted in assuming that both the May-year and the solstitial year are provided for. Regarding the base line as of first importance, we have May-year, solstitial, and stellar circles of one and the same cultural type. For an explanation of this variety in unity we need, for one thing, a new survey of all the Pictish circles on the plan suggested by Dr. Browne. JOHN GRIFFITH.

Thorpe's Dictionary.

A Dictionary of Applied Chemistry. By Sir Edward Thorpe. Assisted by Eminent Contributors. Vol. 2: *Calculi to Explosion.* Revised and enlarged edition. Pp. viii + 717. (London: Longmans, Green and Co., 1921.) 60*s.* net.

THE "Dictionary of Applied Chemistry" has now become so indispensable to workers in pure as well as in applied chemistry that it can be stated without fear of contradiction that no library either in the university or in the works can be regarded as complete without it. The appearance of the second volume of the new edition following so closely on that of the first will therefore be welcomed, and will be taken as an indication that the remaining volumes will be published with equal rapidity. The first feature which is noticeable in the new volume is the decrease in size and the increased handiness compared with the corresponding volume of the last edition. This result has been attained by reducing the number of pages by about eighty and by using a thinner paper, the general effect being to produce a volume which can be held in the hand readily without fatigue. It follows, although it is not specifically stated, that the publishers intend to issue the dictionary in six or more volumes instead of the five which have hitherto sufficed.

The subject-matter in the volume under review therefore comprises part of that issued in vol. 1 of the last edition and part of that which appeared in vol. 2. The last edition of the dictionary was reprinted in 1917 from the revised edition of 1912, but despite the comparatively short time which has elapsed—a period during which little scientific work was done—it has been found possible to introduce much new matter; this is shown by the fact that the subjects dealt with in the present volume occupy 717 pages, whereas in the last edition they filled 547 pages only.

On the whole there is little call for criticism. The article on carbohydrates—one would like to see this name abandoned because, obviously, the sugars of the rhamnose group, $C_6H_{12}O_5$, are not carbohydrates—by E. F. A. is altogether admirable and stands out by itself as an illustration of what can be done by a master of his subject to make a highly complex chapter in organic chemistry interesting to expert and lay-reader alike. On the other hand, the article on camphor is very disappointing. It is difficult to understand what useful purpose can be served by publishing an article on the chemistry of this substance which does not contain one single graphic formula. Had this edition been published thirty years ago there might have been some justification for the inclusion of this article. The articles on carbolic acid and cellulose remain practically unaltered; it is doubtless too soon to expect to find a full description of the many important uses to which these substances and their derivatives were put during the war.

The article on chlorine has been entirely rewritten by H. B., and is an exhaustive account of this element. It contains a vigorous reference to the use of poisonous substances by the Germans during the war, and gives a list of some of those employed. One would like to have seen, however, an article on chemical

warfare (it is not too late, because it can still come under Warfare) in which this important subject would receive full treatment and in which the activities of British chemists would obtain recognition. It is a curious fact that the need for such an article was emphasised by Sir Edward Thorpe himself in the review he wrote on the book published recently by Prof. Moureu in which this distinguished French chemist describes the activities of his own countrymen. In the next edition the article on chemical warfare might well follow that on chemical affinity.

One is glad to note that the old article on vegeto-alkaloids is to be abandoned, and the different subjects are to be treated under their own heads; thus there is an excellent article on cinchona alkaloids by B. F. H. and O. C., which gives a full account of these important substances. The articles on the natural colouring matters and allied substances by A. G. P. are especially noteworthy, as are those on certain drugs, which fall within this section, by G. B. It is articles such as these which render the dictionary indispensable to the research worker, because they give in a clear and concise manner all the essential details of the chemistry of the substances dealt with and do not confuse the issue by a mass of irrelevant data. It is usually difficult to find information of this kind elsewhere.

Of the longer articles on subjects of general interest, those on carbon, coke manufacture, and recovery of by-products by W. A. B. and E. R., copper cyanides by T. E., distillation by S. Y., and gaseous explosion by W. A. B. and R. V. W., have been brought up to date but otherwise retain the features which have rendered them so useful in previous editions.

There are some completely new articles, and, of these, that on colour and chemical constitution by E. R. W. is particularly interesting. Most chemists will be familiar with the book on this subject which the same author contributed to the series of monographs on industrial chemistry edited by Sir Edward Thorpe, and although they may not all agree with many of the views expressed therein, they cannot but acknowledge that the account given is a fair and clear description of our present position in regard to this very complex question. The present article may be described as a *précis* of the book, and is well worth perusal. Another new article is that by J. N. F. on the corrosion of metals. This is a subject which this chemist has made his own, and there are few who can write on it with greater authority. It is well written, and presents the subject from a point of view which cannot fail to be interesting. The article on dyeing remains much the same as in former editions. One wonders if the tables for detecting colours on the fibre, which occupy fifteen pages, are really worth the space. It may be noted in passing that although the excellent article on cholesterol is signed I. S. M., the name of this distinguished lady does not appear among those of the eminent contributors at the commencement of the volume.

J. F. T.

A New View of Fertility.

The Law of Births and Deaths: Being a Study of the Variation in the Degree of Animal Fertility under the Influence of the Environment. By C. E. Pell. Pp. 192. (London: T. Fisher Unwin, Ltd., 1921.) 12*s*. 6*d*. net.

IN the issue of NATURE for September 22, 1921, p. 105, appeared an article on "Causes of Fluctuation of the Birth-rate," the statements and speculations in which are usefully supplemented in the present volume, which is a valuable contribution to the discussion of this important problem. The main thesis of the book is that the decline of the birth-rate is not explicable on the hypothesis that it is due to the deliberate evasion of child-bearing, but that it can be explained as the result of a natural law the function of which is to adjust the degree of fertility to suit approximately the needs of the race. Much ingenuity is displayed in arriving at the conclusion that the response to the action of the environment in the degree of fertility bears an inverse proportion "to the intensity of the nervous charge," and that the principle involved is a law governing the union of sperm cell and ovum. Unlike Doubleday, whose theory was that a plethoric condition of the organism is unfavourable to fertility, Mr. Pell regards food as only one factor and thinks there is good reason for believing that cerebral development and mental activity are far more important than the supply of food. In this respect his theories approximate to the well-known views of Herbert Spencer as to the inverse relationship between ability to maintain individual life and the ability to multiply.

The arguments by which the above propositions are supported are ingenious and suggestive, although occasionally weak and doubtful points are presented with as great confidence as strong arguments. Thus the author argues from very imperfect data that the sale of contraceptive articles does not take place on a scale large enough to account for the lowered birth-rate, and he assumes the accuracy of the limited data available as to sterility and small families in circles where contraceptive methods are or are not practised. Such data would need to be corrected for age distribution of the married couples under comparison and for the duration of marriage before valid inferences could be drawn. Even then it would scarcely be practicable

to correct for the varying prevalence of gonorrhœa, a chief cause of sterility, and of syphilis, a chief cause of still-births and miscarriages.

On the other hand, the author makes valuable use of illustrations given by Darwin and others of the varying fertility of animals under domesticated conditions. It is evident that there is in this direction a line of valuable investigation into the laws governing fertility which has hitherto scarcely been explored. The evidence is none the less valuable because throughout this book it is pressed into service in support of the author's hypothesis that increasing nervous energy, high feeding, and diminished physical labour reduce fertility, whether in mankind or in the highly bred racehorse.

Travel and Exploration.

(1) *Hints to Travellers. Scientific and General.* Tenth edition. Revised and corrected from the ninth edition, edited for the council of the Royal Geographical Society. By E. A. Reeves. Vol. 1, *Surveying and Practical Astronomy.* Pp. xv+470. Vol. 2, *Meteorology, Photography, Geology, Natural History, Anthropology, Industry and Commerce, Archaeology, Medical, etc.* Pp. vii+318. (London: The Royal Geographical Society, 1921.) 21*s.* net (two vols.).

(2) *Camping and Woodcraft: A Handbook for Vacation Campers and for Travellers in the Wilderness.* By H. Kephart. New edition, two volumes in one. Pp. 405+479. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1921.) 16*s.* net.

BOTH these books are written for the traveller, but they look upon his needs from different points of view. In their scope and appeal, no less than in their style, they differ widely. The first may be said to minister to the intellectual needs of the traveller, the second to his material wants.

(1) "Hints to Travellers," which now reaches its tenth edition, has been known for many years as an almost indispensable volume for the traveller who aims at doing any useful scientific work. Mr. Reeves's volume on surveying and practical astronomy must have found its way into more remote corners of the world than any other book except the *Nautical Almanac.* The present edition has been revised, particularly as regards the second volume, but the general plan of the book remains unchanged. The addition of a few pages devoted to marine invertebrates would not be amiss in the natural history section, and might help to direct attention to an aspect of collecting which many travellers are prone to overlook.

(2) Mr. H. Kephart's aim is to teach the traveller how to live rather than to take observations and record facts. The two volumes, which are bound together, deal respectively with camping and woodcraft. They have grown from an earlier single volume which was published in 1906 and was devoted entirely to travel in the wilds. The author now appeals to a wider public, and devotes much attention to the growing class of holiday-makers who camp, not from necessity, but by choice. For the benefit of the latter there are chapters on fixed camps and camp furniture. The chapter on camp cookery is most elaborate. Mr. Kephart expects campers to live well—his dishes and recipes take us far from the simplicity of oatmeal, bacon, and tea, which are so often the staples of camp life—but evidently the amateur camper in America does not risk any hardship or privation. The chapters on tents, bivouacs, clothing, camp-fires, packs, and cave exploration, to mention only a few, are full of useful hints, even if some of them are too obvious to merit inclusion. There are useful remarks on axemanship, and well-illustrated notes on knots and hitches. The notes on accidents and emergencies are most practical. Altogether Mr. Kephart's book makes fascinating reading, and, even if primarily designed for life in the forests of North America, it should prove useful to campers all the world over, and should certainly find a place in every boy scout library.

R. N. R. B.

Our Bookshelf.

Introduction to Textile Chemistry. By H. Harper. (Life and Work Series.) Pp. ix+189. (London: Macmillan and Co., Ltd., 1921.) 3*s.* 6*d.*

LARGE extensions in the work of elementary education, provided in the Education Act of 1918, have given rise to the necessity for providing books of a new type. Whether the increased facilities for education offered by the Act are ever to materialise cannot yet be stated, but the series in preparation by Messrs. Macmillan and Co., three volumes of which have been issued, seems to provide a type of book which should have a very beneficial influence on education beyond the elementary-school standard. One of the arguments against education is that it unfits the "worker" to perform his daily routine. Even the least intelligent critic would probably admit that a workman is not less useful when he knows something about the material he handles and the machinery which manipulates it. The "Life and Work Series" will assist education which, without being narrowly utilitarian, takes as a basis the life and work of man—a wide enough scope for any educator.

The present volume is evidently the work of an experienced teacher. The reviewer has taught students of a textile centre on similar lines, and he is of opinion that the book should be most successful. Wool has, no doubt on account of the locality of the author's school, a more prominent place than cotton, which will make

the book less useful in Lancashire. In the reviewer's opinion it would be better to have a separate book dealing with cotton in more detail. The paper, printing, and illustrations are excellent.

Ancient Tales from Many Lands: A Collection of Folk Stories. By R. N. Fleming. Pp. 193+ix plates. (London: Benn Bros., Ltd., 1922.) 10s. 6d. net.

IN bringing together this collection of tales Miss Fleming has cast her net wide. Japan, China, India, North America, Egypt, Mesopotamia, ancient Greece, and the British Isles, to name only some of the sources, have contributed to a whole which, viewed merely as a collection of folk-tales, is charming both in subject-matter and in style. The author has, however, had more in view than to provide a pleasant pastime for an idle hour. Her aim has been to present in these traditional stories, in which the spirit of the original is preserved as nearly as possible, a picture of the culture and modes of thought of primitive and early historic peoples in a form that can be utilised and interpreted by the teacher, whether of history or social geography, and at the same time appreciated by the child. Miss Fleming adds in an appendix three essays in which she expounds her philosophy of the use of the folk-tale in education and the principles of selection. If any further indication were needed of the thought, wide reading, and experience which have been laid under contribution in the making of this book, it would be afforded by these essays.

Confectioners' Raw Materials: Their Sources, Modes of Preparation, Chemical Composition, the Chief Impurities and Adulterations, their More Important Uses, and Other Points of Interest. By J. Grant. Pp. viii+173. (London: Edward Arnold and Co., 1921.) 8s. 6d. net.

THE author of this little volume set himself no light task in attempting to provide a handbook suited to the needs of students taking organised courses of instruction in the principles governing confectionery practice. These students usually possess little or no knowledge of elementary science, while, on the other hand, their subject enters many and varied fields of scientific inquiry with which it is by no means easy to deal in simple language. In our opinion the author has skilfully compressed into a small volume and in a readable form a mass of information, hitherto available only in a scattered and relatively difficult literature, which should be of much assistance to the students concerned. A useful introduction is followed by chapters on alcoholic beverages used as flavouring agents, carbohydrates, fruits, essential oils, eggs, and egg products; there is also a useful outline of the methods employed in the analysis of raw materials. The book is by no means without imperfections. The sections dealing with botanical subjects need revision by a botanist, whose recommendations would certainly include suggestions for alternatives to some of the illustrations on p. 101. Again, a bibliography which gives as consecutive entries "Bolton and Revis—*Fatty Foods*," and "Britannica—*Encyclopaedia*," clearly needs drastic revision. Further, the sub-title could easily be improved.

Cocoa. By Edith A. Browne. (Peeps at Industries.) Pp. viii+88. (London: A. and C. Black, Ltd., 1920.) 2s. 6d. net.

WE have had much pleasure in reading this well-illustrated little book, which is a notable addition to a useful series. Miss Browne, who has first-hand knowledge of the Gold Coast, takes her readers on a personally conducted tour through the cocoa-growing districts of the Gold Coast Colony and Ashanti, which, as most people know, now form the premier cocoa-growing region of the world. The information conveyed in this interesting fashion is complete, accurate, and well arranged, and is supplemented with admirable glimpses of West African life. Balance is given to the book by an account of cocoa-growing in other countries, followed by a description of the manufacture of cocoa products in two well-known English factories. Miss Browne finds opportunity to warn the West African cocoa industry of the potentialities of South American cocoa-growing countries now deprived of their former pride of place. The warning is well timed and merited, not solely on the grounds mentioned by the author.

A Star Atlas and Telescopic Handbook (Epoch 1920) for Students and Amateurs. By A. P. Norton. Pp. 34+16 maps. (London: Gall and Inglis, 1921.) 10s. 6d. net.

A NEW edition of this useful atlas and astronomical handbook has been published. The maps are clearly printed on a scale of 8° to the inch, and they include stars down to the sixth magnitude, with many fainter objects of interest. The letterpress contains an explanation of all ordinary astronomical terms and much information on both the solar and the stellar systems, together with hints on the use and care of the telescope. There is a clear lunar map, with the names of the principal formations.

A few errata may be noted: on p. 6, along the circles of 6h. and 18h. R.A. declination and latitude have the same direction; on p. 10 the annual P.M. of Groom. 1830 is 7″, not 17″; the magnitude of the Barnard star in Ophiuchus is 10, not 13; and on p. 11 the object entered in the nova list at the date A.D. 389 was certainly a comet and never went near the constellation Aquila. The information given, however, is full and accurate with very few exceptions.

A. C. D. C.

The Practical Electrician's Pocket-book for 1922. Twenty-fourth annual issue. Edited by H. T. Crewe. Pp. lxxxiii+558+54. (London: S. Rentell and Co., Ltd., 1922.) 3s. net.

WE can recommend this pocket-book to all who are practically engaged in any of the industries in which electricity is used. This edition has been revised and contains new sections dealing with tungar rectifiers, railway signalling and current limiters. The latter are devices which either cause the consumer's lamps to flicker in an intolerable way or to become dim if he tries to take more than his permissible current.

The Age of Power: A First Book of Energy, its Sources, Transformations, and Uses. By J. Riley. Pp. viii+248. (London: Sidgwick and Jackson, Ltd., 1921.) 4s. net.

DESIGNED originally for use in continuation schools,

this book will be found equally suitable for the middle forms of secondary schools. Containing, as it does, excellent descriptions of the mode of working in windmills, the steam engine, the internal combustion engine, hydraulic, steam, and internal combustion turbines, etc., it cannot fail to interest boys and to increase their interest in their physical studies. There is enough, but not too much, speculative matter included to stimulate the thoughtful reader. We can thoroughly recommend the volume as providing a useful addition to the ordinary school course.

An Introduction to the Physics and Chemistry of Colloids. By E. Hatschek. (Text-Books of Chemical Research and Engineering.) Fourth edition, entirely rewritten and enlarged. Pp. xiv+172. (London: J. and A. Churchill, 1922.) 7*s.* 6*d.* net.

MR. HATSCHEK'S book is one of the best introductory text-books on the subject in any language, and is widely appreciated. The present edition has been rewritten and enlarged, and embodies much of the recent work on the subject. It should be in the hands of all students of chemistry, and for this reason it is much to be regretted that the price is not lower.

The Manufacture and Uses of Explosives, with Notes on their Characteristics and Testing. By Dr. R. C. Farmer. (Pitman's Technical Primer Series.) Pp. xii+116. (London: Sir I. Pitman and Sons, Ltd., 1921.) 2*s.* 6*d.* net.

ALTHOUGH interest in the military applications of explosives has probably waned to a considerable extent in most countries, it is perhaps not generally realised what an important part these products of chemical invention play in the arts of peace. The name of the author of this small book is sufficient to guarantee the accuracy of the information contained in it, and it is only necessary to state that Dr. Farmer has compressed into about a hundred small pages a surprising amount of up-to-date material. The style is easy, but the treatment is such that the book is far from being merely a "popular" account of the subject: it is a small encyclopaedia, which may be read with advantage by all students of chemistry as well as by those more directly interested in the manufacture and uses of explosives. The very important source of sulphur at Louisiana should have been mentioned on p. 37.

Directive Wireless Telegraphy: Direction and Position Finding, etc. By L. H. Walter. (Pitman's Technical Primer Series.) Pp. xii+124. (London: Sir I. Pitman and Sons, Ltd., 1921.) 2*s.* 6*d.* net.

IT is now thirteen years since Bellini and Tosi read their paper on "A Directive System of Wireless Telegraphy" to the Physical Society of London. Although Marconi and Fleming had previously done good work on directive radio-telegraphy, it was this paper that first showed British physicists how directive signalling could be obtained by using a fixed aerial and only rotating a small coil of wire. The method, however, lay almost dormant until the war proved its great practical utility. Mr. Walter was one of the pioneers of the Bellini and Tosi system, and in the volume under notice a *résumé* is given of most of the useful practical information available. The author has utilised much of the theory recently published by the Bureau of Standards and by the Signal Corps of the United States War Department. The mathematics given is of the most elementary description, and will be readily understood by every physicist and engineer. We can commend this book.

Fuel and Lubricating Oils for Diesel Engines. By W. Schenker. Pp. xii+114. (London: Constable and Co., Ltd., 1921.) 15*s.*

THE title of this book is apt to convey a wrong impression, as its contents in the main are of a general character, and not specially devoted to Diesel engines. There are three sections, the first of which deals with the origin and preparation of various kinds of fuel oils, with special reference to the varieties which may be used for Diesel engines; the second section treats very briefly of lubricating oils; whilst the third consists of a description of the commercial tests applied to these oils. The book would have been of greater service to British consumers of oil had the author included a fuller account of the methods of testing and forms of specification used in this country instead of confining himself to Continental practice in these particulars. Thus Redwood's viscometer, the British standard instrument, is dismissed in a dozen lines, and Abel's flash-point apparatus is not mentioned. Descriptions of other appliances are sometimes too meagre, the bomb calorimeter being given only eleven lines, whilst a purifying apparatus, illustrated on p. 66, is entirely undescribed in the text. In spite of these drawbacks, however, the book contains much useful information of a practical kind. C. R. D.

The Wonder Book of Science. By J. H. Fabre. Pp. 287. (London: Hodder and Stoughton, Ltd., n.d.) 8*s.* 6*d.* net.

THE object of Fabre in writing the series of essays under notice was to impart general knowledge about things that are familiar to the eyes, though not necessarily to the understanding. The first seven essays deal with insect-life, and these are followed by a number on birds, on some of the facts of plant-life, on the various forms of water and the application of steam, on the elementary phenomena of electricity, etc. These essays, which touch on so many subjects, illustrate Fabre's method of arousing the interest of young people in the phenomena around them. In all, forty-eight essays are reproduced, but the name of the translator does not appear.

More Hunting Wasps. By J. H. Fabre. Translated by A. T. de Mattos. Pp. viii+376. (London: Hodder and Stoughton, Ltd., n.d.) 8*s.* 6*d.* net.

THROUGH the energies of the late Alexander de Mattos a number of Fabre's most interesting studies in insect-life have been rendered accessible to the general reader in this country. The present volume consists of fourteen chapters, which complete the essays in the "Souvenirs Entomologiques" devoted to wasps. The remainder have already been translated in two earlier volumes entitled "The Hunting Wasps" and "The Mason Wasps." Two of the essays in this book, which form chaps. 2 and 10, have already appeared in previous translations, while the remainder are rendered in English for the first time. Most admirers of the writings of the French *savant* will welcome the appearance of this book and revel in the fascinating

stories of insect behaviour that are recorded in its pages. Fabre is admittedly a difficult writer to translate, and the charm of his diction only too readily escapes if too much freedom be exercised. Mr. de Mattos's task, therefore, has not been an easy one, but he has carried it out conscientiously and with evident care for accuracy.

A First Book of Applied Electricity. By S. R. Roget. (First Books of Science.) Pp. viii + 143. (London: Macmillan and Co., Ltd., 1921.) 2s. 6d.

THE author has made a very successful attempt to give the elementary principles which underlie the useful applications of electricity and magnetism without worrying the reader with academical definitions and difficulties. The book has what we think is a great merit—namely, that it is entirely independent of the requirements of examinations. It is therefore more interesting than the ordinary treatise, and covers a much wider field.

It can be recommended to the general reader anxious to get an easily acquired, accurate, and useful knowledge of electrical matters. The ordinary student reading for examinations will also find it a useful introduction to more advanced treatises.

Perfumes, Essential Oils and Fruit Essences used for Soap and other Toilet Articles. By Dr. G. Martin. (Manuals of Chemical Technology.—X.) Pp. vii + 138. (London: Crosby Lockwood and Son, 1921.) 12s. 6d. net.

DR. MARTIN's book is of a severely practical character; it contains much information in a very condensed form, and should be useful as a work of reference to those interested in the manufacture of the class of materials of which it treats. A large number of practical recipes is given. The section on analysis, occupying only four pages, is too brief to be of real value. No references to the literature are given beyond the mention of a few patents and a list of ten books on the subjects treated.

"*Power's*" *Practical Refrigeration.* Compiled by the Editorial Staff of *Power.* Pp. viii + 283. (New York and London: McGraw-Hill Book Co., Ltd., 1921.) 10s. net.

THE practice of ammonia refrigeration, including a simple account of the theory and tables of useful constants, is discussed in this volume. A number of practical hints for users of refrigeration plant, written in a colloquial style, forms about half the book, which should be useful to persons in charge of such plant.

Chemistry of Pulp and Paper Making. By E. Sutermeister. Pp. vii + 479 + 31 plates. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1920.) 36s. net.

THE chemical aspects of paper-making are dealt with in the volume under notice, the mechanical processes being described only in so far as they are necessary for an understanding of the chemistry. Although concerned chiefly with American practice, and less complete than the standard English treatises, the volume should be of service to chemists in paper-works laboratories. It is clearly written and well illustrated.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Directive Tendency of Elongated Bodies.

THIS letter deals with several topics, perhaps somewhat remotely related to one another, but all suggested by previous letters on the same general subject in NATURE of October 20, November 24, December 1, and December 22, 1921.

In my letter of December 22 it was suggested that Mr. Reeves's results might be explained by the peculiarities of the gravity field at the place where the experiments were made. The letter was written before Mr. Reeves's letter appeared and while I was under the impression that his experiments were all made at one place. The suggestion might be plausible as regards any one place, at least until measurements had been made there with an Eötvös balance, but would be highly improbable when applied to every one of the widely scattered places where Mr. Reeves made his tests.

Col. Grove-Hills in his latter in NATURE of November 24 directs attention to an important difference between the turning effect of the earth's field on an elongated body supported at its centre of gravity and the turning effect on a similar body when supported by flotation. He attributes quite undeserved credit to me, however, in stating that this matter is fully treated in my article in the September (1921) issue of the *American Journal of Science.* Only a very special case of the turning effect on a floating body is there treated, and that case is scarcely analogous to the one considered in recent issues of NATURE.

There are two kinds of forces acting on a floating body, namely, the force arising from the earth's gravity field, which is a body force, and the normal pressure of the fluid on the wetted surface. By well-known theorems concerning the transformation of surface integrals into volume integrals it may be proved that the effect of the fluid pressure may be replaced by the body force arising from the earth's field reversed and applied to a solid bounded by the wetted surface and by the free surface of the fluid extended in imagination into the floating body, the density of this solid being the same as that of the fluid. This theorem is proved in very elementary fashion in the ordinary theory, in which gravity is assumed to be constant in intensity and direction, but is equally true when gravity varies in intensity and direction from one part of the region considered to another.

In dealing with the turning effect on a floating body of the earth's field and of the fluid pressure, it is necessary to make some assumption regarding the depth to which the body is submerged; a natural assumption is that the body is submerged to such a depth that the downward pull of the earth's field is just balanced by the upward thrust of the fluid pressure or of the equivalent body force. Let us consider the case of an elongated body symmetrical about a vertical axis through the centre of mass of the body, and let us suppose the earth's field to be also symmetrical about the same axis; there is then no moment tending to turn the body about any horizontal axis. Several terms disappear from the general expression for the earth's field on account of the assumed symmetry, but those remaining represent the component of a force that turns the suspended elongated body about into the prime vertical for a normal field

of force, or in any case into the vertical plane where the curvature of the equipotential surfaces is a minimum. The turning moment of the direct effect of the earth's field about a vertical axis is precisely the same for the floating body as for a like body when suspended. For the total effect of the floating body we must consider also the turning moment of the fluid pressure, or of the equivalent body force, and this, in general, opposes the direct turning effect of the earth's field.

For a body like an elongated right cylinder the two turning effects practically cancel each other, so that the resultant is an infinitesimal of higher order, so to speak, than either turning effect by itself. It is possible, however, by varying the shape of the elongated body to make one or the other tendency prevail. If the body overhangs the fluid considerably, like the bow of a racing yacht, the direct effect of the earth's field has the advantage of position in producing a turning moment, and in the normal case the tendency of the body is to turn into the prime vertical, just as for the suspended body. If the body has its extreme end submerged, thus resembling the mirror images of the ends of the overhanging body, then the contrary tendency will prevail, and in the normal case the body will tend to set itself in the meridian. This tendency to seek the meridian would not, however, be true of all elongated floating bodies of dimensions comparable with those of the Eötvös balance, as Col. Grove-Hills would seem to imply.

My own interest in the effect of the earth's gravity field on floating bodies was due originally to an attempt to account for certain hypothetical displacements of each continental mass as a whole towards the equator. These displacements are believed by a well-known geologist—who for the present, however, does not wish to be quoted by name—to be established almost beyond question. His ideas differ somewhat from those of Prof. Alfred Wegener, of Marburg, who has published much regarding supposed continental displacements. The problem of the equilibrium of the mass of self-attracting gravitating fluid rotating about an axis, with a mass of lighter matter floating in the fluid and projecting out of it, is apparently one of considerable difficulty, especially if we consider the gravitational effects of the floating body on the field of force. Considerations of symmetry would lead us to suppose, however, that the floating body would not be in stable equilibrium at any random point on the surface of the body; the equator of the rotating fluid seems a natural place for stability, and a calculation of the forces acting shows that there is, in fact, a tendency for a floating body to move towards the equator—a tendency stronger, in general, the higher the body floats above the free surface of the fluid.

The difficulty with this equatorward tendency as an explanation of the supposed movements of the continental masses is that the movements appear to have occurred after the earth's crust was well consolidated and there could be no longer any question of floating continental blocks. There is, to be sure, a region of weaker and softer crust around the edge of each continental block, where a sort of syncline dips into the warmer regions nearer the centre of the earth. (All this geology is at second hand, or worse, and should be accepted only with appropriate reservations.) There would be also the weakness underneath the continental mass due to the heat there. In a way this condition resembles that of a floating body, and if for any reason the continental mass should move, the region of weakness around its edges would move with it. However, it does not seem especially probable that the weak gravitational field that tends to move a floating body towards the equator could accomplish very much in moving a continent that forms part of a fairly well consolidated crust.

Even though the equatorward force on a floating body may not be manifest in the displacement of continents, it may perhaps be discernible in the motions of much smaller floating bodies, namely, icebergs. The higher the iceberg the stronger this force. The acceleration may be written approximately for the normal case as

$$\frac{d}{a}\Delta g \sin 2\phi,$$

where d is the distance between the centre of gravity of the floating body and its centre of buoyancy, Δg the difference between the acceleration of gravity at pole and equator, ϕ the latitude, and a the radius of the earth. An iceberg 200 metres in height is rather exceptional for Arctic latitudes, but in Antarctic waters a height of 500 metres (1700 ft.) has been reported (see "The Seaman's Handbook of Meteorology," published by H.M. Stationery Office for the Meteorological Committee, third edition, pp. 132-35). If we suppose the icebergs to be plateaux with wall-sides and to have only one-eighth of their masses above the water, the values of d corresponding to visible heights of 200 and 500 metres would be 100 metres and 250 metres respectively.

The value of Δg is 5·18 cm. and of a $6{\cdot}37 \times 10^8$ cm. The maximum value of the equatorward acceleration on the two icebergs, which occurs in latitude 45°, would be 0·000081 and 0·000203 cm. per sec. per sec. respectively. At latitude 60°, the latitude of Cape Farewell in Greenland, these figures would be reduced to 0·000070 and 0·000176 cm. respectively; but even the smallest of the four accelerations acting for an entire day would, if unresisted, set the iceberg in motion, give it a velocity of more than 6 cm. per sec. at the end of the day, and move it 2·6 km. At the end of twenty days the velocity would be 1·2 metres per sec. and the displacement 1050 km., or more than nine degrees of latitude. With greater acceleration the effects would be greater in proportion.

It is fairly certain, however, that the resistance of the water would prevent the iceberg from actually attaining any of the larger velocities. Probably the terminal velocities from these small forces are of the order of magnitude of a very few centimetres per second. The dominant forces are the winds and currents, but these small forces arising from the earth's field would act more effectively on the higher icebergs and bring them more rapidly into low latitudes. One gets the impression in reading accounts of ice observed in low latitudes that large icebergs are the rule there rather than the exception. There are some obvious reasons for this. The large icebergs are less apt to be overlooked and better able to survive the warm weather than are the small ones. The selective effect of the earth's field is merely an additional reason for the frequent occurrence of large icebergs in low latitudes; to say how important a reason it is would seem to require more data than we now have.

Revival of Sporophores of Schizophyllum commune, Fr.

As has been pointed out by Prof. A. H. R. Buller ("Researches on Fungi," 1909, p. 113), sporophores of *Schizophyllum commune* which have curled up as the result of definite xerotropic action can be revived by suitable treatment in a moist chamber. The following illustrations afford interesting photographic confirmation of Prof. Buller's experiments :—

Fig. 1 shows a group of dry sporophores on their original matrix, bark of *Populus sp.*, four months after collection, and Fig. 2 a similar group of the same gathering after revival.

It has been remarked, but not further emphasised by Prof. Buller (*loc. cit.*), that the pileus of *S. commune* is of an absorbent nature. Indeed, the pileus shows a remarkable avidity for water, and the hairs composing the woolly covering of the pileus enable it

FIG. 1.—Xerotropic form of *Schizophyllum commune*. Natural size.

to absorb moisture with a greater rapidity than is usual in fungi, so far as I am aware.

The moist condition of the edge of the pileus remote from the matrix, immediately after wetting the latter, and rendered evident by the transition from snow-white to a silvery-grey colour, led to several experiments. It was found that the application of a drop of water to one edge of a dry pileus resulted in an immediate, and apparently uniform, diffusion of moisture throughout the woolly covering of the whole pileus—about 1·5 cm. diameter. The rate of absorption is much greater than that seen in the absorption

FIG. 2.—*Schizophyllum commune* after revival. Natural size.

of ink by blotting-paper, and this fact was more convincingly demonstrated by the use of a dilute aqueous solution of methylene-blue.

It seems reasonable to suppose that the possession of this property will enable the fungus, in its xerotropic condition, to take the fullest advantage of any raindrop that may fall upon it by instantly absorbing it. This supposition was tested by allowing drops similar in size to tropical raindrops to fall from a height on to the pileus, and it was observed that each drop was immediately absorbed, without splash, until saturation point was reached. Were its absorbent power less, much water would be lost to the fungus on account of its sharply convex outline.

Conservation of water, in the case of a group, is assured by the imbricate habit of *S. commune*. The pileus of a plant growing at the top of a group of sporophores collects all the raindrops that reach it until it becomes saturated, after which the surplus drips on to the pileus of a plant below, and so on, until a whole group has obtained its full requirements without the loss of a single drop.

The moisture-content of the fully expanded fungus and of the xerotropic form respectively are given below. They are the results of one determination only in each case. The specimens were dried in a water-oven at 99°-100° C. for five hours with all the precautions usually taken in the estimation of moisture.

Normal sporophore .	water = 84·3 per cent.
Xerotropic form .	water = 16·0 per cent.

I am indebted to Messrs. Murphy and Son, Ltd., for the use of the accompanying photographs, and to Mr. W. N. Cheesman, of Selby, for the specimens, which were collected at the Worcester foray of the British Mycological Society in September last.

F. A. MASON.

Bureau of Bio-Technology, Leeds.

Statistical Studies of Evolution.

I SHOULD like to suggest that the curves shown by Dr. Willis and Mr. Udny Yule in their article in NATURE of February 9, p. 177, are capable of a different interpretation from that which the authors place upon them.

It is possible that the curves are not, so to speak, a function of the organisms themselves, but rather of their environment.

Consider a habitable area of large size such as a continent. The environment will vary in character in different parts of the continent, the variation being due to the presence or absence of environmental limitations such as warmtn, moisture, particular food, etc.

In the continent considered, the greater the number of environmental limitations in any area the greater will be the number of possible combinations of these limitations. Thus there will be in the continent a great many different kinds of environment with a large number of limitations (such as mountain peaks, deserts, salt marshes, etc.), far fewer kinds of environment with a moderate number of limitations, and still fewer with a small number of limitations.

Since the continent we are considering is large, we can consider it to be divided evenly between areas with many limitations down to areas with few limitations. But we have already seen that there are many kinds of environment possible in areas with many limitations, and therefore each of these areas with one particular environment will be of small size.

Conversely, the areas with fewer possible kinds of environment and few limitations will be large in size.

In fact, could we plot the number of kinds of environment possible in any one size of area against size of area, we should obtain the same type of hollow curve as that obtained by Dr. Willis.

Assuming, as is legitimate, that, on the whole, organisms are adapted to their environments, it follows that areas with many limitations will require many adaptations in the constitution of the organism, and therefore few organisms will live in these areas, and these will be highly adapted types or species.

Hence the small areas with many limitations will each possess a few characteristic species; and since

there are very many such small areas, we see that there will be very many species which occupy small areas.

We can obtain, in fact, Dr. Willis's (number of species) against (size of area) curve simply by assuming (1) that in any very large area the distribution of different kinds of environment is random, and (2) that organisms are adapted to their environment.

I therefore come to conclusions exactly opposite to those of Dr. Willis, for I think we have in his curves direct evidence that:—

(1) Evolution has proceeded almost entirely by natural selection adapting a species to the limitations of its environment.

(2) Animals are so closely adapted to their conditions of existence that it is impossible to conceive of evolution proceeding by the large mutations suggested by Dr. Willis.

Space prevents me considering here Dr. Willis's (number of genera) against (number of species) curves, but these also are susceptible of a similar interpretation in terms of natural selection.

C. F. A. PANTIN.

Christ's College, Cambridge, February 16.

WE find it very difficult to follow the hypotheses made by Mr. Pantin in his interesting letter, and cannot agree that they accord with reality. We cannot see how, for example, the hypothesis that natural selection is the dominant factor affords any explanation of the fact that the numbers and proportions of local species increase towards the south; nor how it can explain the fact that in New Zealand (*cf. Ann. of Bot.*, vol. 32, 1918, p. 339) a great many families show their maximum number of endemics in every genus at the far north, all these families being Indo-Malayan; while a second group of families, characteristic of the northern hemisphere, show their maximum number at the south of New Zealand, and a third group at the centre. The northern families and genera diminish as one goes southward in New Zealand, and pass over, without paying any attention to, the regions where the maxima of the central and southern groups occur. These groups in the same way show no unusual change when they reach the region where the northern maximum occurs. Are the environmental conditions so peculiar at these points that those of the north should cause a multiplication of species only in Indo-Malayan families, and those of the south only in families of the northern hemisphere?

J. C. WILLIS.
G. UDNY YULE.

Columnar Structure in Sandstone Walls of a Glass Furnace.

IN the issue of NATURE for December 29, 1921, p. 567, I described the occurrence of columnar structure in optical glass and in fireclay.

Through the courtesy of Mr. Currie, of the Scottish Central Glass Works, Alloa, I had recently an opportunity of examining columnar structure that had developed in the lowest sandstone course of the side walls of a small tank glass furnace. The walls comprised two upper courses of fireclay blocks, in which no columnar structure developed, and the bottom course of rough-grained sandstone blocks obtained from the Penshaw Quarries, Durham. Their cross-section was about 1 sq. ft. Firebrick jack-arching formed the floor of the tank, under which was situated the regenerator.

The sandstone course was laid in August 1913, and taken down in November 1921, during which operation the structure was observed.

When emptying the tank the floor failed, and the glass discharged itself through a space between the floor and the regenerator roof. Thus while the walls were rapidly chilled the floor was maintained at a comparatively high temperature.

The accompanying photograph (Fig. 1) is of one typical fragment taken from the inner surface; other portions showed curvature of the columns, which at

FIG. 1.

the upper end were nearly normal to the corroded Λ-shaped surface of the joint, and at the lower to the bottom surface of the block.

The similarity between these sandstone specimens and those of optical glass previously illustrated is worthy of remark.

JAMES WEIR FRENCH.

Anniesland, Glasgow, February 13.

The Action of Sunlight: A Case for Inquiry.

READERS of NATURE are no doubt aware that the Medical Research Council has just appointed a Committee on the action of light upon the human body in health and disease, thus meeting the need which I have been allowed to urge in these columns under the above heading (NATURE, December 8, 1921, and January 5).

I see no end to the inquiries in which we are now at last to participate in England, the country the smoke-darkened cities of which need them most. Before me now is a series of papers which I owe to Dr. A. F. Hess, of New York, who has demonstrated that sunlight can cure or prevent rickets in human infants and animals irrespective of the absence or presence of the supposed anti-rachitic vitamin. Again, along this coast, from Cannes to San Remo, I find French and Italian clinicians at work curing what I have called the diseases of darkness by sunlight; also a voluminous literature, as yet entirely unknown in England, which raises questions of high racial, genetic, and eugenic importance, such as the influence of sunlight, or the lack of it, upon the normal development of the reproductive system and its functions during adolescence. But clinicians elsewhere had assured me—and I fear I may have repeated their statements in these columns—that the sun-cure cannot be practised on the Riviera!

Never henceforth, I predict, will the columns of NATURE cease to bear records of the new study of the biology of light now to be begun.

The Mechanism of Heredity.[1]

By Prof. T. H. MORGAN, Columbia University, New York City, U.S.A.

II.

Linkage and Crossing-over.

MENDEL'S second law has been found to be restricted in its application. Two pairs of characters do not always assort independently. This fact was first observed by Bateson and Punnett in 1905, and called gametic coupling—not that gametes (ripe germ-cells) are coupled, but that when certain genes enter together from one parent they tend to hold together, as though coupled, in later generations. A specific case will serve to illustrate this kind of inheritance.

If a sweet pea with genes for purple flowers and long pollen grains is crossed to a pea of another strain with red flowers and round pollen, the expectation for the two pairs of genes would be in F_2 9 : 3 : 3 : 1. Instead of this ratio there was found approximately 177 : 15 : 15 : 49. Purple long and red round have come out in the second generation in unexpected ratios, or, in other words, the results are explicable only on the hypothesis that the genes that went in together have shown a tendency to stay together instead of freely assorting.

This coupling is often spoken of to-day as linkage, because it applies not only to two genes, but to any number of them. A few further cases may be given; in one the characters, as in the pea, are not sex-linked, and in the other they are. There is a strain of *Drosophila melanogaster* that is black. It gives with the wild fly in the second generation a 3 : 1 Mendelian ratio. There is another strain that has vestigial wings. It, too, gives with the wild fly a 3 : 1 Mendelian ratio. It is easily possible to make a strain that is pure both for black (*bb*) and for vestigial (*vv*). If a black vestigial male (*bv*) is mated to a wild female (B V) (grey long wings) all of the offspring are grey long (Fig. 11). If one of the F_1 sons is mated to a black vestigial female of pure stock, only two kinds of offspring are obtained; half of them are black vestigial, and half are grey long. In other words, the two recessive characters that went in together (black vestigial) have come out together. These characters are completely linked in the male. It may be said, in exactly the same sense, that the other two characters, the dominant ones, namely, grey long (which went in together from the other side), are also linked. Now if the genes for black and for vestigial are carried in the same chromosome, then their partners or allelomorphs (grey long) lie in the other chromosome of the same pair, and if these chromosomes remain intact the result is what is expected to take place.

Linkage is also excellently illustrated in the case of sex-linked characters. As has been shown, white-eye *versus* red-eye colour of Drosophila gives a Mendelian ratio. Another sex-linked character, yellow colour, also gives the same result. If a strain is made up that has white eyes and yellow colour, and if a female of this strain is mated to a wild-type fly (red eyes, grey colour), all the sons will be white-yellow, and all the daughters red-grey (Fig. 12). If these are inbred, the great majority of the offspring (98·5 per cent) are yellow-white and grey-red (half and half). In other words, these characters are linked, but only in 98·5 per cent. of the cases. The remaining 1·5 per cent. is composed of two kinds of individuals, red-yellow and white-grey. It may be said, therefore, in this case, that the white eye of the yellow type has crossed over to the grey type, and in exchange the red eye of the grey type has crossed over to the yellow type.

The four kinds of offspring obtained in this cross can be accounted for, if once in a hundred times an interchange has taken place between the two X-

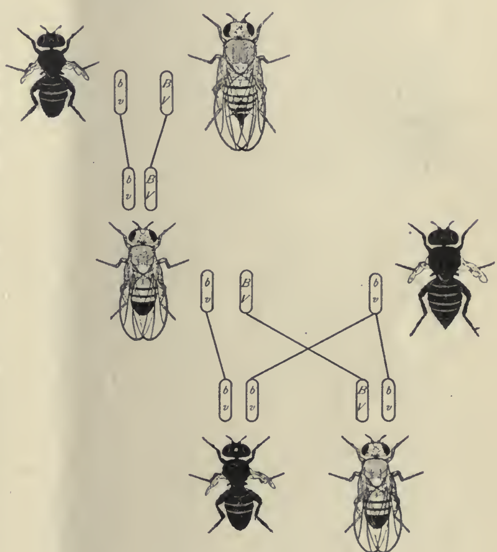

FIG. 11.

chromosomes of the F_1 female, in such a way that the part containing the gene for white eye is interchanged for a corresponding part of the other chromosome with the gene for red eye.

Another example of crossing-over may be given, one involving the same characters, black and vestigial, which were used to illustrate complete linkage. It is possible to use the same combinations of characters to illustrate both absolute linkage and crossing-over, because in the male of Drosophila there is no crossing-over, but in the female crossing-over occurs. Therefore, in the first case above, in which this combination was utilised, an F_1 male was back-crossed, while in the present case an F_1 female will be employed. If, as shown in Fig. 13, a black vestigial fly be crossed to a wild-type fly (long wings, grey), the F_1 female will be wild-type. If she is back-crossed to a black

[1] Continued from p. 244.

vestigial male of pure stock, the F_2 offspring will be of four kinds, in the proportions given below:—

Non cross-overs		Cross-overs	
Black vestigial	Grey long	Black long	Grey vestigial
41·5 per cent.	41·5 per cent.	8·5 per cent.	8·5 per cent.
83 per cent.		17 per cent.	

In this experiment 17 per cent. of crossing-over occurs in the F_1 female. As before, the relation of these facts to the chromosomes is illustrated by the rods in the centre of the diagram. The two pairs of elements (genes) involved are indicated by the letters inside the rods.

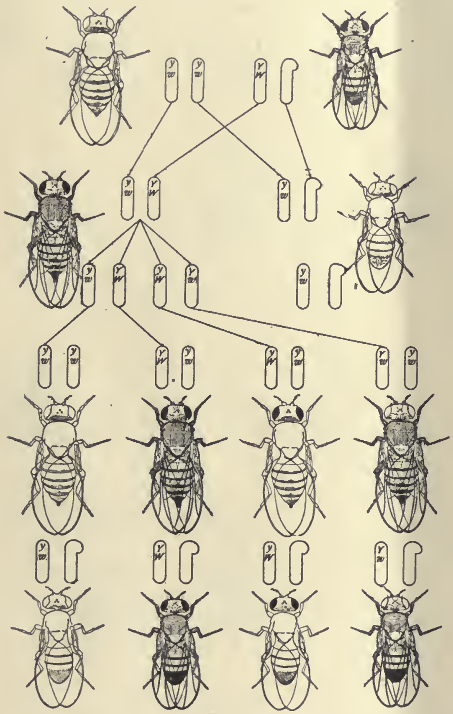

FIG. 12.

Many examples of linkage and crossing-over are known at the present time. Linkage is said to be strong when, as in the yellow-white case, crossing-over takes place in a small proportion of cases. Linkage is said to be weak when crossing-over takes place frequently. Crossing-over may be less than 1 per cent., or even not take place at all (complete linkage), as in the case of the black vestigial male given above. It may take place in nearly 50 per cent. of the individuals of a back-cross, which means that about half of the flies show linkage, and half show crossing-over. This would be, of course, numerically the same result as when the two pairs of characters involved freely assort. A case of this kind could not, in fact, by itself alone be distinguished from a case where the pairs are carried by different chromosomes. It may appear, therefore, incorrect to speak here of linkage, and this would be true were there no other evidence showing that the two characters involved are in the same chromosome. But whenever a number of other characters are known in the same group the linkage of the two characters giving 50 per cent. of crossing-over can still be shown, for if each of the characters is found to be linked to a third one they must be linked to each other.

In Drosophila there are more than one hundred sex-linked characters. If their linkage relations are studied *in series* an important result comes to light. This may be illustrated by the following example. It has been stated that crossing-over takes place in 1·5 per cent. of cases between yellow colour and white eyes. There is another eye character, called echinus,

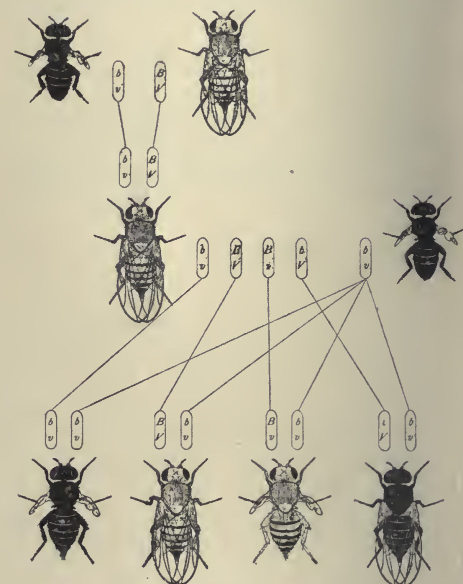

FIG. 13.

that gives 5·5 per cent. of crossing-over with yellow (Fig. 14). If, now, the position of echinus is represented as 5·5 units of distance from yellow, then its "distance" from white must be either $5·5+1·5=7·0$, if it lies to the "north" of yellow, or else $5·5-1·5=4·0$ if it lies to the "south." In fact, when the experiment is made, the percentage of crossing-over between white and echinus is found to be 4·0.

There is another sex-linked character, ruby, that gives 7·5 per cent. crossing-over with yellow. If it lies to the north of yellow it must give with echinus $7·5+5·5=13$; or if to the south of yellow, $7·5-5·5=2·0$. It is found to give 2 per cent. of crossing-over. Hence, lying south of yellow, it should give with white 6·0, and this is what is found.

Such a method of analysis can be followed step by step until the whole of the sex-chromosome is plotted. This procedure has a twofold significance. First, if a new mutant character is found, its "linkage-group" is first made out; then its "distance" from any one

member of that group is determined. It is then necessary to find its position with respect to another known member of the group (preferably one near by) which determines whether it is north or south of the first member. Once this has been done, the method of inheritance of the new character with all other members of its group can be worked out on paper from the crossing-over data, plotted as distance. In other words, the heredity of this new mutant, with all the other known characters of Drosophila, can be predicted, since, with its normal allelomorph, it will give a 3 : 1 ratio; with any character in another group it will give a 9 : 3 : 3 : 1 ratio; and with other members of its own group it will give a definite result which can be calculated from the "distance" of the plotting.

The second point of significance concerning the plotting of the genes in terms of distances is as follows: the discovered relation of genes, as expressed in distances, is one that holds for points in a line. This means that if the genes in question are represented in space, their relation to each other is that of points in a line. If the line is a chromosome, then the chromosomes are to be thought of as made up of a single line of genes. The reasons for referring the genes to the chromosomes have already been given. The possibility of explaining crossing-over on a chromosome basis will be discussed later.

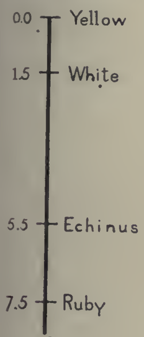

FIG. 14.

There is one situation where, on superficial examination of the data, an apparent disturbance of the linear order may appear, namely, when crossing-over takes place at two levels in the same linked series at the same time (double crossing-over). But by marking intermediate points between the extreme ones all double cross-overs can be detected and the distances corrected for them. When this is done, it at once becomes apparent that the linear order is the correct arrangement of the genes. In fact, far from throwing doubt on the linear order, these cases, where double crossing-over occurs, furnish a strong corroboration of the correctness of the hypothesis.

The use of the word "distance" as an expression for the percentage difference in crossing-over values does, unfortunately, lend itself to misunderstanding, unless one knows just what meaning is attached to the word when used as defined above. An example will make this clear. If crossing-over is more likely to occur in one region of the linear order than in other regions, the plotted "distances" will be relatively too short in comparison with the distances of the remainder of the series. Distance, therefore, must be understood in a relative, not in an absolute, sense. We have been aware of the necessity of this restriction from the beginning of our studies of the linear order of the genes, and have warned others of the danger in numerous publications, but apparently without complete success. It has also been shown that the percentage of crossing-over changes under external (Plough) and internal (Bridges) conditions. As the female gets older, crossing-over becomes less in some cases, hence the "distances" appear to become less. It has also been shown by Sturtevant that genetic factors may exist that affect the crossing-over in certain regions of the linear series, in one case shortening that region to zero, since all crossing-over is suppressed. But the significance of this result, from our present point of view, is that when the shortening factor is removed (by a definite genetic procedure) the original distance of the genes in this region reappears, *and the genes are shown not to have changed their original order.* This reassures us that the linear order stands on a firm basis. A recent attack on the theory of the linear

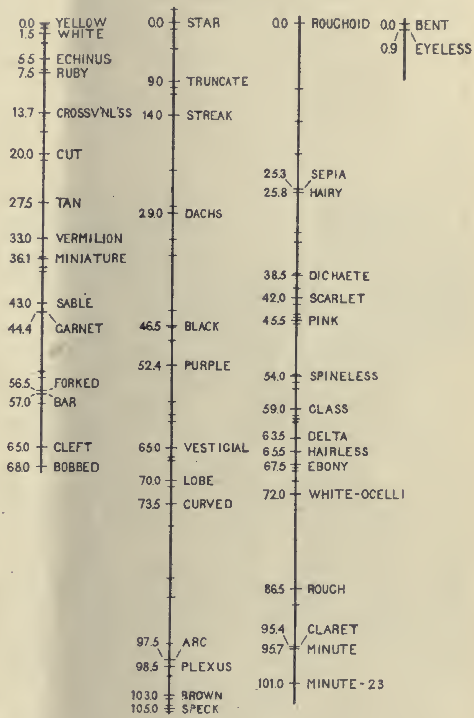

FIG. 15.

order is based on evidence that shows that "through selection" the distances between certain genes changed. The result really has no bearing on the point, because the order of the genes was not shown to have been affected. Moreover, Sturtevant's case, more thoroughly worked out, shows that where even greater changes of distance had taken place the order of the genes had not changed.

The plotting of the linear order of the genes in the four chromosomes of *Drosophila melanogaster* is shown in Fig. 15. The four great groups of linked genes are represented by straight lines with the approximate positions of the genes indicated by short cross-lines. The numbers opposite these cross-lines give the distances from a base chosen as far "north" as possible. The location of some of the genes rests on an immense

amount of data; other genes are less accurately placed. Still others, not so well determined, have been omitted from this diagram.

The localisation of the genes has been calculated from numerical data independently of any assumption as to how crossing-over takes place in the animal. Perhaps it might be safer to let the matter rest on the genetic evidence alone in the present uncertain frame of mind of most cytologists concerning the conjugation of the chromosomes at maturation; but there are at least certain facts admitted by a number of cytologists concerning the maturation of eggs and sperm that seem to fall into line with the simple mechanism that the genetic evidence for crossing-over calls for. This evidence may next be considered.

(*To be continued.*)

Science in Poland.

DURING the past seven years Poland has suffered all the miseries of war. Amid the desolation in which the country was plunged, the votaries of science did their best, until 1919, to uphold the interests of study and education against inimical and contending Governments; since the Polish State was resuscitated they have been engaged in laying the foundation of the work of the future. In 1914 only two Polish universities (Cracow, Lwów) were in existence; in 1922 five large State-endowed universities are actively

FIG. 1.—Interior Court of the Library of the Jagellonian University, Cracow, with the statue of Copernicus.

at work; the University of Warsaw was started in 1915, those of Poznan and Wilno in 1919. Centres of technical teaching and research are springing up; in Warsaw and Lwów important colleges of mechanical and electrical engineering, of applied chemistry, of architecture, etc., are well attended, and in 1919 a High School of Mines was established in Cracow. These institutions are sufficiently equipped with appliances required for practical teaching.

Agricultural science also receives a good deal of attention; in addition to faculties or other schools of university rank existing in Cracow, Warsaw, Lwów, and Poznan, a National Institute of Agricultural Research was founded in Pulawy in 1917. This institute is under the direction of Profs. Godlewski and Marchlewski, and shows a remarkable completeness of arrangement. For the study of the mineral resources of Poland, a National Geological Institute was created in 1920 in Warsaw, under Prof. Morozewicz; a branch institution in Cracow, under Dr. Nowak, has for its object the investigation of oil-bearing regions. An Epidemiological Institute, a Central Meteorological Office, and a Natural History Museum have been constituted; but within the brief compass of an article it is impossible to do more than refer simply to the fact of their inauguration.

At the head of Polish educational institutions stands the Jagellonian University of Cracow, founded by Casimir the Great, King of Poland, in 1364. In 1400 the university was restored and enlarged by King Ladislas Jagello, who thus complied with the last wish of his universally honoured and beloved wife, Queen Jadwiga. At the end of the fifteenth century the university was at the height of its influence and fame; there was probably no contemporary school in Europe where mathematics and astronomy were prosecuted with more zeal and success. An undergraduate matriculated in the university in 1491 who was to transmit his name to the remotest posterity. At that time Wojciech Brudzewski (Albertus de Brudzewo) had attained a wide and established reputation as an astronomer, and it was probably by him that young Copernicus was taught to employ his genius.

In the seventeenth and eighteenth centuries the university suffered much from the insecurity of the times, and for many years was on the decline. A new epoch began about 1870; an impulse was given to study, and research, although hampered by financial embarrassments, had greater importance assigned to it than at any previous period. Among the mathematicians of that period are Mertens, Baraniecki, and Zrawski; Rudzki did creditable work in geophysics, especially seismology; Zygmunt Wróblewski and Karol Olszewski, by their activity in the domain of low temperature research, achieved success that shed lustre on the Cracow laboratories; Witkowski, by the pains he took to ensure accuracy, paved the way for much subsequent thermodynamical investigation; Smoluchowski (whose untimely death, in 1917, was a matter of universal regret) accomplished brilliant work, largely influencing progress towards a kinetic theory of matter. Within the precincts of the Jagellonian University, Janczewski, E. Godlewski, Sen., Rostafinski, Raciborski, Rothert, Kulczynski, Prazmowski, Wierzejski, Jentys, Adametz, Majer, Kopernicki, and Talke-Hryncewicz — names well known to students of

botanical, zoological, or anthropological science—were engaged in teaching and research. The medical faculty will always be associated with the names of Dietl, Teichmann, Cybulski, Browicz, Jordan, Pieniazek, Korczvnski, Jaworski, Mikulicz, Rvdygier, Wicherkiewicz, and others.

The Jagellonian University always consisted, and now consists, of four faculties. The faculty of theology has nine professors; the faculty of jurisprudence has sixteen professors and four lecturers; while the faculty of medicine includes twenty-six professorial chairs and thirteen lectureships. The philosophical faculty embraces literature and philology, history and philosophy, mathematical, physical, and natural science; in connection with this faculty there is a college of agriculture, a department of pharmacy, and a teachers' training school. No less than sixty-eight professors and twenty-two lecturers are engaged in the work of this faculty. The total number of matriculated students during the session 1921–22 is 4631.

Space will permit only of a reference to the library of the university (Biblioteka Jagiellonska), renowned for the precious MSS. it contains.

L. N.

Current Topics and Events.

THE national manifestation of rejoicing on the occasion of the marriage of H.R.H. Princess Mary to Viscount Lascelles on Tuesday, February 28, is a sign of the secure place which the Royal Family occupies in the hearts of the British people and also, we hope and believe, a token of national unity. In common with all classes of the community, workers in scientific fields marked the occasion with affectionate interest and shared with much satisfaction in the chorus of good wishes by which the nation expressed itself in perfect harmony with a happy event.

THE following fifteen candidates have been selected by the Council of the Royal Society to be recommended for election into the Society:—Prof. T. H. Bryce, Mr. C. G. Darwin, Dr. C. G. Douglas, Dr. S. R. Douglas, Prof. A. J. Ewart, Dr. A. Hutchinson, Dr. F. W. Lanchester, Mr. J. Mercer, Prof. S. R. Milner, Prof. M. S. Pembrey, Prof. F. Lee Pyman, Prof. G. A. Schott, Dr. N. V. Sidgwick, Mr. D. M. S. Watson, Sir Alfred Yarrow, Bart.

THE Report of the Aeronautical Research Committee on the causes which led to the loss of the airship R. 38 was issued by the Air Ministry on February 23. The Committee has come to a number of clear findings and has summarised them at the end of its report; it has concluded, from an examination of the evidence available, that the airship broke in two as a result of defects in design, but that the loss of life was to be attributed largely to a subsequent fire. It appears that the only calculations made by the designers were of the type used in general engineering and had little special reference to airships. In addition, no account was taken of the aerodynamic forces which an airship might reasonably experience in normal usage. Information as to the importance of the air forces is said to have existed from experiments on models of airships in the wind tunnels, but the warning was not acted upon even to the extent of referring the problem to the Aeronautical Research Committee. Shortly expressed, the result of the enquiry shows the marked deficiency of rule-of-thumb as compared with scientific methods as an instrument of progress. The accounts of the accident in America to the semi-rigid airship, *Roma*, further point the moral. The obvious fundamental fact in engineering design is that the details of a structure should depend on the forces it has to withstand. In an airship the bending arises in part from the distributed weights and in part on aerodynamic loading, the former being independent of the speed of flight and the latter to its square. Hence an airship moving at 30 knots may have the stresses due to weight and buoyancy twice those due to aerodynamic causes, whilst at a speed of 60 knots the proportions are exactly reversed. The accident to R. 38 appears to have occurred when the air loading was at least five times that provided for by the designers on the basis of weight alone. There is great difficulty in introducing improvements into aircraft with the present official organisation, and it is to be hoped that the report will receive due consideration from the point of view that it is desirable to provide for scientific progress rather than for a process of trial and error on a large scale and at great expense in life and money.

THE third and final Report of the Committee on National Expenditure (Cmd. 1589, price 4*s*.), issued on February 24, deals, among other services, with the British Museum, National Gallery, National Portrait Gallery, Wallace Collection, London Museum, Imperial War Museum, Geological Museum, and National Galleries (Scotland). The Estimates for 1921–22 and the Provisional Estimates for 1922–23 are respectively £506,771 and £405,864. Over 80 per cent. of the Estimate is in respect of the cost of personnel. The Committee thinks that further economies might be produced by a close investigation into the size of the warding staff, especially in the case of the British Museum and the Natural History Museum. It recommends that there should be four paying days a week for all National Museums and Art Galleries without distinction. The Committee is of opinion that the net sum of £405,864, which is asked for in the Provisional Estimates for 1922–23, should be reduced to £392,264, a saving of £13,600. With regard to the grants for scientific investigation, amounting in all to £200,423, it is recommended that the grant to the Medical Research Council—£130,000—should be as proposed by the Treasury. As regards the smaller grants, the Committee says: " We are averse from an arbitrary and uniform reduction on a percentage basis on the ground that the saving to the Exchequer would be small compared with the detriment which would be caused to the activities of the learned and scientific world and the discouragement which would be given to private subscriptions and donations if the Exchequer grants were reduced. We therefore recom-

mend that the Provisional Estimate, as framed by the Treasury, should be accepted, with the qualification that it may be possible, under the terms of the Irish Settlement, to omit £2200 proposed for the four Academies and Societies in Ireland. The Department of Scientific and Industrial Research was instructed, in May last, to effect at least a 20 per cent. reduction on expenditure. The Department succeeded in effecting this, and presented a Provisional Net Estimate of £330,287. Since arriving at that figure the Department and the Treasury have agreed on an additional cut of £17,700, and, as the result of a further review, the Department have intimated that a still further reduction can be made, which will bring their Net Estimate down to £298,071. We are unable to recommend any further reduction beyond the saving of £32,216 already effected."

THE Minister of Health announced last week that the Rockefeller Foundation had offered a sum of two million dollars (approximately £454,000 at the present rate of exchange) for the provision of an institute of State Medicine in London—site, building and equipment—on the understanding that the British Government accepted the responsibility for staffing and maintenance. At present public health teaching is given at some seven or eight institutions in London, which instruct about 120 students per annum for the examinations for the Diploma of Public Health; for toxicology and medical jurisprudence practically no advanced course is available. The need for an Institute of State Medicine has long been recognised, and some years before the war the Board of Hygiene of the University of London formulated a scheme for the provision of such an institute, but funds for its establishment were never forthcoming, and in 1921 the Committee for post-graduate medical education in London made a similar recommendation. The offer of the Rockefeller Trustees has been gratefully accepted by the Minister of Health, and the Government proposes, we believe, to allocate a sum of £25,000 annually for the maintenance of the Institute, the work of which will be devoted both to education and to research in all branches of State Medicine.

ON Wednesday, March 1, there was opened at the British Museum a special exhibition of Greek and Latin papyri presented at various dates by the Egypt Exploration Society. This body (formerly the Egypt Exploration Fund) is celebrating the twenty-fifth anniversary of the foundation of its Graeco-Roman Branch, the excavations of which at Behnesa (Oxyrhynchus) and elsewhere have made so many additions to our stock of Greek literature and to our knowledge of the political, economic, and social history of Graeco-Roman Egypt; and it is in honour of the anniversary that the Museum is arranging its exhibition. A guide-book to the exhibition, with introduction, detailed descriptions of the papyri shown, a preface by Sir Frederic Kenyon, and one photographic facsimile, is being published by the Society, and will be on sale at the Museum, price 1s. The exhibition, which will be found in the MSS. Saloon, Case A, includes many interesting papyri of various kinds, selected to illustrate the wide range of papyrological discovery. There are examples of famous additions to Greek literature, like the Paeans of Pindar, the poems of Cercidas, and the Oxyrhynchus historian; theology is represented by the Sayings of Jesus; and the economic and social life of Egypt finds illustration in many non-literary documents, several of them rich in human interest.

THE Referee, under section 1 (5) of the Safeguarding of Industries Act, has given judgment against the complaint of the British Cellulose and Chemical Manufacturing Company, Limited, that calcium carbide had been improperly excluded by the Board of Trade from the lists published by them of articles chargeable with duty under Part I. of the Act. The effect of the award is that calcium carbide is not to be subject to import duty.

THE ambitious project for opening up a navigable channel of sufficient width and depth to enable ocean-going vessels to reach the group of inland ports fringing the shores of the Great Lakes of North America, and there to ship and discharge their cargoes direct without any intermediate handling, is steadily being urged in influential quarters, and, despite strong and determined opposition, appears to be gaining ground. The report of the International Commission, which has been holding an inquiry into the feasibility, necessity, and cost of the scheme, has just been presented to the respective Governments at Washington and Ottawa. The position may be briefly summarised as follows:—At the present time vessels loaded with grain at the great depôts of Port Arthur, Fort William, Duluth, and Superior, on Lake Superior, and of Chicago and Milwaukee, on Lake Michigan, are unable, on account of the rapids on the St. Lawrence, to proceed further than Buffalo, at the lower end of Lake Erie, where the grain has to be transferred either into barges to proceed along the Erie Canal to New York for reshipment or into small ships capable of traversing the Welland Canal as far as Montreal, where again reshipment is required for the ocean journey. This repeated handling of the cargoes means increased cost of carriage, delay, and dearer bread for the countries to which the grain is consigned. The necessity for transhipment can be avoided only by the formation of a waterway of sufficient capacity for ocean-going vessels, and, as contemplated in the proposed scheme, this means the enlargement and deepening of the Welland Canal from a depth of 25 ft., to which it is at present being increased, to a depth of 30 ft., and the construction of four lateral canals and impounding dams at the rapids on the St. Lawrence River, together with the deepening of the river-bed itself. There is an additional advantage attaching to the scheme in that by the construction of the dams a very considerable amount of hydro-electric power could be developed, and it is claimed that on this ground alone the project should prove a sound and profitable enterprise.

WE learn from *Science* that Capt. Roald Amundsen has made arrangements for co-operative work in

terrestrial magnetism and atmospheric electricity with the Department of Terrestrial Magnetism of the Carnegie Institution of Washington throughout his forthcoming expedition to the Arctic regions. During the North-East Passage, 1918–21, the Amundsen Expedition made a series of highly valuable magnetic observations at rather more than fifty different points, and Capt. Amundsen's chief scientific assistant, Dr. H. U. Sverdrup, has been associated with the Department of Terrestrial Magnetism since last October in order to complete the reduction and publication of the magnetic observations thus far obtained by the expedition. He will rejoin the *Maud*, Capt. Amundsen's vessel, early in March at Seattle. It is expected that Capt. Amundsen will resume his Arctic expedition, the chief object of which is to obtain scientific data relating to geography, oceanography, meteorology, gravity, terrestrial magnetism, and atmospheric electricity, about June 1.

H.R.H. The Duke of York will open the Research Laboratories of the British Cotton Industries Research Association, Shirley Institute, Didsbury, Manchester, on Tuesday, March 28. The opening ceremony will take place at 3.30 P.M.

THE Société Genevoise d'Instruments de Physique informs us that it has not at the London address, 95 Queen Victoria Street, E.C.4, a specimen of the printing chronograph referred to in Our Astronomical Column on February 16, p. 217.

THE trustees of the Percy Sladen Memorial Fund have given a substantial grant towards the expenses of the expedition to S.W. China by Prof. J. W. and Mr. C. J. Gregory, who are leaving for Rangoon at the end of March. The expedition will therefore be conducted as one of the Sladen Trust Expeditions.

PROFESSOR NILS BOHR, of the University of Copenhagen, will give a course of five lectures on the "Quantum Theory of Radiation and the Structure of the Atom" in the Cavendish Laboratory, Cambridge, on March 6, 7, 10, 13, and 14, at 4·45 P.M. The last two lectures, of a more advanced character, will deal with "Selected Problems in the Theory of Atomic Constitution."

THE members of the Geologists' Association of London are about to entertain at dinner their retiring President, Mr. William Whitaker, F.R.S. Mr. Whitaker, who is in his 86th year, joined the Geological Survey in 1857 and the Geologists' Association in 1875. He has frequently served as a member of the Council and has conducted innumerable excursions. He was President from 1900 to 1902, and has recently completed a second term of office. The dinner will be held on Saturday, March 25, at Stewart's Restaurant, 50 Old Bond Street, W., at 7 o'clock. A large attendance is expected.

AT a joint meeting of the Faraday Society and the Oil and Colour Chemists' Association, to be held on Thursday, March 9, at 8 P.M., in the rooms of the Chemical Society, Burlington House, W.1, a group of papers will be presented dealing with the properties of powders considered from various aspects. Prof. T. Martin Lowry and Mr. L. C. McHatton will deal with the grading of powders by elutriation, Prof. P. G. H. Boswell will contribute a paper on elutriation from the point of view of the geologist, and Dr. J. W. French will speak on grinding and polishing powders. Dr. R. S. Morrell, Mr. C. A. Klein, and Mr. W. J. Palmer will discuss the subject from the point of view of the oil and colour chemist, and Mr. R. W. Whymper will deal with certain applications to cocoa and chocolate. The subject will then be thrown open for general discussion.

Our Astronomical Column.

RELATION OF SPECTRAL TYPE TO MAGNITUDE.—The Henry Draper Catalogue of the Spectra of Stars, which is now completed but not yet fully published, contains as many as 225,000 stars. The classification is based on the Harvard system, wherein more than 99 per cent. of all the stars fall into the six main groups designated by the arbitrary letters B, A, F, G, K, and M. It is now known, from the work of Lockyer and Russell, that the actual sequences of changes in a star's spectrum are from M to B as the star increases in temperature (giants), and from B to M as the star cools (dwarfs). Thus for each letter mentioned above there are two distinct kinds of stars, and the nearer the letter is to M the greater this distinction becomes. It is necessary, therefore, to bear this fact in mind when reading the Harvard College Observatory Circular (No. 226) on the relation of spectral type to magnitude by Dr. Harlow Shapley and Miss Annie J. Cannon. Of the numerous tables given in the paper the following abstract of one of them exhibits some of the main results of the investigation.

The second column may be considered as representing the distribution of naked-eye stars among the various spectral classes. It will here be seen that the hot A stars exceed in number those of any other type, the cooler K class running it a close second. This state of things is reversed in the three following columns, which show a drop in magnitude for each

Spectral division	Visual magnitudes brighter than			
	6·25	7·25	8·25	9·25
B	719	1,286	2,061	3,026
A	2,018	5,904	15,884	39,342
F	680	2,160	6,536	15,224
G	656	2,456	8,776	27,160
K	1,984	6,144	20,760	51,008

column. In all columns, however, the A and K type stars are prominent features. In discussing the frequency of spectral divisions for successive fainter magnitude intervals, the B type stars rapidly fall off as fainter stars are considered. The A stars fall off to about the 8th magnitude, but then rapidly rise again. The F and M types maintain their frequency nearly throughout to magnitude 8·5, but fall slightly afterwards. The frequency of the G type increases very rapidly throughout the whole series up to magnitude 9·5, while the K class increases up to the 8th magnitude and then falls off. A plate accompanying the paper shows graphically many of the features of the tables.

MAYA HIEROGLYPHS.—Though much attention has been bestowed on the decipherment of the Maya hieroglyphs since a key was supplied by Diego de Landa, the first Spanish bishop, the result, except as regards some numerals, has been disappointing. It is obvious that the way to begin such a study is by an examination of the modern language of the country, as the study of Coptic has helped in ancient Egyptian. Hitherto the grammars of the Maya tongue have supplied an inadequate basis for its study, because their authors, Spanish priests, were ignorant of philology and phonetics and tried to build up a grammar of a primitive language by following the Latin or Spanish models. This naturally led to two classes of defects: unnatural forms were invented to express corresponding ideas in Latin or Spanish, and numbers of native expressions were overlooked because they could not be brought within the European system. Mr. A. M. Tozzer, the first travelling fellow in American ethnology of the Archæological Institute of America, spent a considerable time in Central America, from 1901 to 1905, and he issued in 1907 a report of his ethnological work. This he has now followed up by a comprehensive grammar of the Maya language on modern lines and a bibliography of the literature. He omits any discussion of the phonetic character of the Maya hieroglyphs, and he deals with the language as unrecorded up to the time of the Spanish conquest. But he justly remarks that any elucidation of the hieroglyphs will be impossible until an advance is made in our acquaintance with their phonetic elements. This in recent years has not advanced in comparison with the gains made in deciphering the numerical parts of the hieroglyphic writing. A successful correlation of the modern Maya language with the hieroglyphs holds out a prospect of success. In this respect Mr Tozzer's book, forming vol. 9 of the Papers of the Peabody Museum of Archæology and Ethnology, Harvard University, deserves hearty commendation.

MARINE MOLLUSCAN FAUNA OF AMERICA.—A useful summary of the marine shell-bearing molluscs of the north-west coast of America has been published by Mr. W. H. Dall (U.S. Nat. Mus. Bull. 112, pp. 217, 22 plates). In the preparation of this summary the results of more than fifty years' study of the molluscan fauna of the north-west coast have been brought together, Mr. Dall's investigations having begun in 1865. The molluscan fauna of this coast falls into three main divisions—the Arctic, containing many circumboreal species, and extending from the Arctic Sea to the southern limit of drift-ice in winter in the Bering Sea; the temperate, extending from this line southwards to Point Conception, California; and the tropical, from the latter place to Point Aguja on the coast of Peru. The total number of species (excluding nudibranchs and cephalopods) for the region is 2122. The Tertiary and Pleistocene fossils of the shores of Bering Sea afford evidence of a communication with Atlantic waters during the prevalence of more genial conditions. Several species now living in Bering Sea are found fossil in the late Pliocene of Nantucket and the Pliocene of Iceland, and, conversely, the common periwinkle of New England (*Littorina palliata*) is one of the species found in the elevated beaches of Nome, Alaska, and is now extinct on the Pacific coast. The intercommunication between the two oceans would seem to have been tolerably free at the time, though now there are quite pronounced differences between the Greenlandic and the Bering Strait Arctic assemblages of molluscs.

A PARASITIC AMŒBA WITH PATHOGENIC CAPACITIES.—Prof. C. A. Kofoid and Dr. Olive Swezy have recently described (Univ. California Zool. Publ., vol. 20, No. 7), under the name *Councilmania Lafleuri*, a parasitic amœba of the human intestine which "appears to have pathogenic capacities." They state that this organism is apparently cosmopolitan in distribution, but has hitherto been confused with *Entamoeba coli* because of its eight-nucleated cyst. The cyst has a thick wall, and in addition to the eight nuclei, each with a large dispersed karyosome, there are in the protoplasm acicular chromatoid bodies, fasciculate or massed in the later phases. The cysts are spheroidal, ellipsoidal, or asymmetrical, and their non-spherical form and the dispersed karyosome are among the characters given to distinguish this new amœba from *E. coli*. In fresh stools the cysts exhibit a process of repeated budding, resulting in the escape of amœbulæ. Protoplasm issues through a minute pore formed in the cyst-wall, a nucleus slips out into the protoplasmic bud, and this bud detaches itself as an amœbula. A new bud is formed and creeps away, and so on until as many amœbulæ have been produced as there were nuclei. The authors are emphatic that this is a normal process. They state that in the division of the nucleus in the cyst eight chromosomes are demonstrable at the metaphase, whereas *E. coli* has only six. In ordinary practice there will be great difficulty in distinguishing the active stages of Councilmania from those of *Entamoeba histolytica* and the cysts from those of *E. coli*. The reason for creating the new genus Councilmania is not obvious, and is not stated by the authors.

BUD MUTATIONS.—That bud sports, or bud mutations, frequently give rise to important new varieties has long been known. Darwin studied many such cases, and Cramer in 1907 compiled an account of all the cases then known. Mr. A. D. Shamel, in a recent publication of the Experiment Station of the Hawaian Sugar Planters' Association, describes and clearly illustrates many modern instances. He believes that in many plants the selection of bud mutations is quite as important as seed selection in the origination of new varieties. Such occurrences are notoriously frequent among citrus fruits, where many often occur on the same tree, but they are also relatively common and have given rise to new varieties in potatoes, sugar-cane, apples, peaches, and pears, as well as in grapes, plums, strawberries, and a great variety of cultivated garden-plants, such as dahlias, chrysanthemums, roses, and carnations. Less is known concerning the frequency with which they will come true from seed, and this, of course, lessens their evolutionary significance.

PRESERVATION OF THE KAURI PINE.—Most of the Kauri pine, *Agathis australis*, the finest conifer south of the equator, has been destroyed in New Zealand by the lumberman. It is satisfactory to learn from the State Forest Report for 1920–21 that a remnant of the primeval forest of this species near Dargaville, 908 acres in area, was acquired by the State last year, and will be preserved intact as the National Kauri Park. An illustration in the report shows the stem of one veteran which is 36 ft. in girth. Other forests, of which the Kauri is an important constituent, need not, however, disappear. Investigations commenced a year ago by Mr. W. R. McGregor show that this species is readily regenerated under the shade of a natural-shelter wood. Complete re-establishment of a felled area requires a period of

twenty-five to fifty years, and is effected by the selection method. With proper precautions against fire, the Kauri forests that remain in New Zealand can be so managed as to yield a rich store of timber for centuries to come. The other important conifers in New Zealand, *Dacrydium cupressinum*, *D. Colensoi*, *Podocarpus dacrydioides*, and *P. totara*, also regenerate vigorously, and the process of their regrowth is in evidence in all situations where fire and grazing are excluded.

THE MOSS ROSE.—The origin of the moss rose is the subject of a paper by Major Hurst and Miss M. S. G. Breeze in the current issue of the Journal of the Royal Horticultural Society. It differs from the cabbage rose (*R. centifolia*) only in the much greater development and branching character of the glands on petioles and sepals and the branching of the latter. The cabbage rose has been in cultivation for more than two thousand years, and the earliest record of the moss rose is from Carcassonne, in southern France, where it probably originated as a bud-mutation from the cabbage rose at least as early as 1696. The mossy character has since arisen independently from two other varieties of the cabbage rose. In 1775 the Unique Rose appeared in a garden in the Eastern Counties as a tinged-white variety, and in turn gave rise to the "Unique Moss" through a bud-mutation in France about 1843. The Rose de Meaux is a miniature variety of the cabbage rose which may date from about 1637. A moss mutation appeared from this in the West of England in 1801. Both the moss and cabbage rose are sterile, and there is little doubt that all these derivatives arose from the old cabbage rose as bud-mutations. The records show that at least seven bud-reversions from the moss rose to the cabbage rose occurred in the period between 1805 and 1873. In the half-century following 1788 seventeen varieties of the moss rose appeared, one of which was single and fertile and extensively used in crossing. Twelve of these bud-mutations are parallel to corresponding earlier variations in the old cabbage rose. Bud-mutation is therefore a frequent phenomenon in *Rosa centifolia* under cultivation, and there is, as the authors suggest, a direct connection between this condition and the sterility. The evidence indicates that the mossy character is probably a simple Mendelian dominant.

THE EXAMINATION OF TEXTILES BY X-RAYS.—An interesting addition to the many and varied uses of X-rays in the examination of materials has been developed by Messrs. Truesdale and Hayes in the research laboratory of the Dunlop Rubber Co., Birmingham. In the Journal of the Textile Institute, vol. 12, No. 11, November 1921, they describe how, by the aid of radiography, they have studied the movement of the threads in the canvas of a motor-tyre during the several processes of manufacture of the tyre. For this purpose the canvas was specially woven so that every twentieth thread, both warp and weft, had been previously impregnated with a heavy salt. Thus the X-ray photograph reveals a series of squares, the pattern being in the form of a check. The most suitable salt for the purpose was found to be lead chromate formed by precipitation on the yarn by first soaking it in lead acetate and then in potassium bichromate. The X-ray plates or films were placed in actual contact with the material, so that the dimensions of the radiograph were those of the canvas. In the case of a tyre the film was placed inside the tyre, in contact with the first ply, and held in position by spring clips. The X-ray tube was on the outside, and care was taken that the X-rays were normal to the film. As the series of reproduced radiographs shows, the dimensions of the sides and angles of the squares are affected in some of the processes. By measuring predetermined squares on the radiograph taken after each process the change due to the previous process can be arrived at. The method proves to be an effective means of ascertaining whether the stretch of the canvas threads, resulting from the various processes in the manufacture of the tyre, is within the limits of stretch tolerated by the yarn—a point of extreme importance to the tyre manufacturer.

PROPAGATION OF EARTHQUAKE WAVES.—Dr. S. W. Visser, of the Royal Magnetic and Meteorological Observatory of Batavia, has recently issued an important paper on "The Distribution of Earthquakes in the Netherlands East Indian Archipelago during 1910–19, with a Discussion of Time-tables." For several years the tables in use of the times of transit of the primary and secondary waves as recorded on seismometers have been recognised as requiring corrections, and both Geiger and Gutenberg in Germany and G. W. Walker in this country have made definite suggestions towards this end. By a detailed discussion of the earthquakes having their origin near Batavia, Visser has been able, by means of a careful examination of the records obtained at distant stations, to draw up new sets of tables so far corroborating the suggestions already made, but carrying out the corrections much more completely and through the whole range of distances from the epicentre. The corrections of the primary times of transit are most conspicuous in the range from 50° to 100° arcual distance, being an increase of as much as 10 seconds at the distance of 60° or 70°. In the case of the secondary times of transit the corrections are more in evidence, being a decrease for small arcs (less than 50°), an increase for larger arcs (up to 70°), and a marked decrease for arcs greater than 80°. Visser also discusses what seems to be the manner of propagation of the waves which enter the nucleus of the earth, and gives general support to the views expressed by Knott in his recent paper on the propagation of earthquake waves. In the light of the corrections now supplied it will be necessary to recalculate the forms of the seismic rays, especially for the secondary waves. Visser fully bears out the conclusion already come to that the primary wave ceases to be recorded at distances greater than about 110°, but finds evidence of their reappearance beyond 140° with a retarded time of transit.

HARMONIC DEVELOPMENT OF TIDAL THEORY.—Dr. A. T. Doodson, of the Tidal Institute, University of Liverpool, has just published in the Proceedings of the Royal Society (A, vol. 100, p. 305, 1921) a paper on "The Harmonic Development of the Tide-generating Potential." Since 1883 the development given by Sir G. H. Darwin has been universally used and has proved of remarkable value, but the assumption usually tacitly made, that no terms not included in his schedule need be considered in tidal prediction, has been shown by work at Liverpool on tidal observations to be unjustified. It was therefore decided to make a new development in which, in view of the possibility of terms being magnified by resonance, great accuracy has been striven after. All terms the coefficients of which exceed one ten-thousandth of the leading term are included; this degree of accuracy is unnecessary for practical tidal work, but the needs of research were also kept in mind. Unlike Darwin's development, which was algebraic and founded on the old lunar theory, referring everything to the orbit rather than to the ecliptic, the present work is essentially numerical and strictly harmonic; Brown's new lunar theory is taken as the basis of the development. Many terms which are too large to be ignored for modern purposes, but do not occur in Darwin's schedule, have been found.

The Jubilee of the Institution of Electrical Engineers.

IT is now fifty years since the Society of Telegraph Engineers held its first meeting. The title of the Society was changed to that of the Institution of Electrical Engineers in 1883, and it has grown from a membership of about 100 in 1872 to one of more than 10,000 in 1922. Last year the Institution was granted a Royal Charter, and it celebrated its jubilee last week by holding meetings at which some of the pioneers of electricity gave recollections of the early days of the industry.

Prof. Fleming gave fascinating lectures on Michael Faraday. He showed how well this great investigator laid the foundations on which the impressive superstructure of modern electrical practice has been built. In particular he laid stress on the marvellous thoroughness with which Faraday stated the physical laws of electrolysis and electromagnetism. Many of Faraday's statements which survive intact in our modern text-books are models of lucidity. For its rapid development the industry is largely indebted to the unselfish labours of this great physicist.

Electrical engineering more than any other branch of engineering is based on pure science. The ease with which measurements of the highest accuracy can be made has been the greatest boon to engineers. It is not surprising, therefore, that electrical machines have gradually been evolved the efficiency of which approximates to a hundred per cent. No one appreciates more highly than the electrical engineer the value of scientific research, and no one takes a keener interest in every discovery in pure science.

Many of the reminiscences given by speakers at the commemoration meetings carried us back to the earliest days of the industry. It has to be remembered that the incandescent lamp was invented and the first telephone exchange was built only 44 years ago. Many of the speakers, therefore, had watched the growth of the industry from the start. Several tales were told of the founding of the Institution. It was pointed out that the ideas underlying any new movement are usually present in a vague way in the minds of many people and, therefore, it is difficult to assign the credit for the original idea with any degree of certainty. We think that greater stress might have been laid on the work done by Lord Lindsay—afterwards the Earl of Crawford and Balcarres—in founding the Society. He had a laboratory in a slum called Eaton Place (now swept away), lying between Green Street, Grosvenor Square, and Oxford Street. Some of the apparatus used is still in use at Faraday House, a college and testing institution which he helped to establish in 1889. It was in this laboratory that the first inception of founding a Telegraph Society was made in 1869. Cromwell and Arthur Varley, who worked in it, were anxious that the Society should be started at once, and they particularly wished that Sir William Thomson, who was then the leading electrical expert, should be the first President. It was not, however, until 1872 that the Institution got under way, the first President being Dr. Carl Siemens (Sir William Siemens). In 1874 Sir William Thomson became President for the first time, Lord Lindsay being one of his Vice-Presidents.

Listening to the speakers brought vividly back to the memory the halo of wonder that surrounded many of the early discoveries. The telephone, invented by Alexander Graham Bell, is regarded to-day as a mere domestic appliance. In 1876 the fact that you could hear a whisper at a distance of ten miles was rightly regarded as an almost supernatural achievement. Mr. Kingsbury recalled that Bell and his associates stated in 1877 in their first business circular that they were "prepared to furnish telephones for the transmission of articulate speech through instruments not more than 20 miles apart." To-day conversation has taken place over 5000 miles, and if the necessity ever arose an Indo-European telephone could be made without the need of further research.

Mr. Judd, who has been intimately connected with submarine telegraphy for more than 50 years, pointed out that notwithstanding the fact that hundreds of thousands of miles of submarine cable are now in existence, yet so well had the foundations of the industry been laid by British engineers and men of science that the cables of to-day are of the same general type as in 1866. Sir William Thomson solved the problem of operating submarine cables, first with the mirror galvanometer and then with the siphon recorder. Both instruments remain practically unaltered. The first great change in cable operation was the introduction of duplex working by which messages could be sent simultaneously from both ends of the cable. Judd was convinced that submarine telegraphy would continue to play the *rôle* assigned to it by the early pioneers of drawing together all the nations of the world.

Col. Crompton began electrical work 44 years ago by installing Gramme dynamos and Serrin lamps. He said that he had to learn the technicalities of his art from the telegraph engineers. Accustomed to working with primary batteries they told him that the resistance of the armature should never be less than the resistance of the external circuit. In the year 1883, as the result of an escape of gas, the Ring Theatre in Vienna was burned down with a lamentable loss of life. The Austrian Emperor issued an order that gas lighting would not be allowed in any of the Imperial Theatres. The Vienna Gas Company, therefore, decided to take up the supply of electric light, and they invited Col. Crompton to assist in the design and erection of their Central Supply Station. This installation was the prototype of many central stations built in this country in the early 'nineties.

Mr. Partridge narrated how the Earl of Crawford and Sir Coutts Lindsay installed a portable electric light plant in a yard behind the Grosvenor Gallery in 1883. From this small beginning emerged the Grosvenor Gallery Station, which was the first to adopt the parallel system of using transformers, thus revolutionising all the methods then in use. This station was burned down in 1890. In this year, after overcoming many difficulties, Ferranti successfully transmitted electric power at 10,000 volts from Deptford to Trafalgar Square.

Sir Charles Parsons gave an interesting account of the first turbo-alternator. This machine ran at 18,000 revolutions per minute, the armature of the dynamo being less than three inches in diameter. It was essential to have the diameter small, as otherwise the centrifugal forces called into play would have been prohibitively high. These small machines were used on board ship; they were far from economical, but they worked satisfactorily for several years. The modern large turbine-driven generator constructed on the lines of Parsons' inventions is the most economical generator of electricity from steam at present in existence. All the proposed "superpower" steam stations will be equipped with these sets.

Sir Oliver Lodge directed attention to the invaluable pioneering work in electrical theory done by Oliver Heaviside, who has shown how to calculate the eddy-current losses in cores, and the effects pro-

duced by high-frequency currents in cylindrical wires. His most important discovery, however, was that of the distortionless circuit, a discovery which led to most important practical developments in long-distance telephony both in land and in submarine cables.

References were made to the discovery of X-rays, of radio-telegraphy, and of the atomic nature of electricity.

The Institution of Electrical Engineers has been fortunate in having so many eminent men of science as Presidents in its early days. Lord Kelvin was President three times, and John Hopkinson was President twice. Amongst others we may mention Sir William Crookes, Sir Joseph Swan, and D. E. Hughes. The wonderful physical insight of Sir William Crookes is only now being fully recognised. Many years ago he had visions of electrons and even considered the possibility of isotopes.

The Institution was founded in order to promote the general advancement of electrical and telegraphic science. In its Journal many important scientific and mathematical papers have been published. In conjunction with the Physical Society of London it has published, at considerable expense, *Science Abstracts* for the past 24 years. Its activities are ever widening and we congratulate it on its well-merited success.

The American Association at Toronto.

THE second Toronto meeting of the American Association for the Advancement of Science and of the associated scientific societies, which was held during the last week of 1921, at the invitation of the University of Toronto and of the Royal Canadian Institute, was the seventy-fourth meeting of the association. It was successful in every way, and must go on record as the most satisfactory meeting thus far held, apart from the greater four-yearly meetings. Fourteen sections of the association were represented and twenty-six associated societies. About nine hundred addresses and papers were presented, and the official registration showed an attendance of 1832 persons. The sessions were held in the buildings of the University, which are excellently adapted for such purposes, while the majority of those in attendance were very conveniently housed in the University dormitories. These arrangements proved to be unusually convenient and satisfactory.

On the afternoon of Monday, December 26, the day before the official opening, the secretaries of the sections met with the general secretary and the permanent secretary to discuss some general problems of the association. On Tuesday afternoon Dr. F. R. Moulton, professor of astronomy in the University of Chicago, showed some very fine motion pictures on scientific subjects, illustrating the use of motion pictures in education.

The meeting was formally opened on the evening of Tuesday, December 27, under the able presidency of Dr. E. H. Moore, professor of mathematics in the University of Chicago. The president was introduced by the retiring president, Dr. L. O. Howard, chief of the Bureau of Entomology of the United States Department of Agriculture, who was permanent secretary of the association for many years. Sir Robert Falconer, president of the University, delivered an admirable address of welcome, emphasising the close and friendly relations that have so long obtained between Canada and the United States. This was followed by the address of the retiring president. In the first part of his address, among other interesting things, Dr. Howard directed attention to the fact that the average age of the presidents of the British and of the American Associations since 1895 is about the same, sixty-one years and eleven months for the British and sixty-one years and five months for the American. The second part of Dr. Howard's address dealt with the topic "The War against the Insects." It was pointed out that unceasing warfare must be waged by mankind against the almost countless and omnipresent forms of insect-life, which threaten the very existence of the human race. A report of the latter part of the address appeared in NATURE of January 19, p. 79. The opening sessions were followed by a reception in the room behind Convocation Hall, where members and their friends had an opportunity to meet one another and to examine the fine series of exhibits of scientific apparatus and products brought together by the local sub-committee on exhibits, of which Prof. E. F. Burton was chairman.

The Wednesday evening session in Convocation Hall was of a twofold character. Dr. W. Bateson, director of the John Innes Horticultural Institution, Merton Park, Surrey, who was present at Toronto by joint invitation of the American Association and the American Society of Zoologists, delivered a stimulating address on "Evolutionary Faith and Modern Doubts." He clearly emphasised the point that students of evolution harbour no doubts as to the fact of evolution, but the exact mode of evolution remains still an unsolved problem. He dwelt on the important progress recently made in America in relation to inheritance and the problems of genetics, especially with reference to chromosomes.

At the close of this address the session was transformed into a convocation of the University of Toronto, Sir Robert Falconer presiding, and the degree of Doctor of Science *honoris causa* was conferred on Dr. Bateson, Dr. Howard, and Dr. Moore. A reception followed the convocation.

Sir Adam Beck, chairman of the Hydro-Electric Power Commission of Ontario, addressed a general session on Thursday afternoon under the auspices of Section M (Engineering). His subject was "Hydro-Electric Developments in Ontario," and he showed a series of moving pictures illustrating the various hydro-electric projects in Ontario.

The Thursday evening conversazione in Hart House was one of the greatest social functions ever held in Toronto, and was unique in the history of the association. For three hours the two thousand guests of the University and the Royal Canadian Institute enjoyed the entertainment facilities of the magnificent students' social centre in Queen's Park.

The weather throughout the meeting was fine, though cold enough to be stimulating, and with an almost unclouded sky. The necessity for using artificial ice for winter sports in Toronto furnished an agreeable surprise to those who had anticipated arctic cold.

The Toronto meeting was especially international in character. It emphasised the point that the American Association is an international organisation. Although the majority of its members are now residents of the United States, it was clearly seen at Toronto how much the future of the association depends upon Canadians. The meeting was an occasion for a pronounced increase in the Canadian membership, and it is hoped that the time will soon come when Canadian men of science will all regard the association as theirs. A wonderfully fine

spirit of international good-fellowship and understanding prevailed throughout the meeting.

Sixteen well-attended dinners were held during the meeting by the various groups of scientific workers. The programmes of the sections and of the societies associated with them were generally extensive, and all were interesting and important. Many vice-presidential and presidential addresses were given and many symposia held. Special mention should be made here of the fine programme of Section M (Engineering) and of the symposium on an international auxiliary language, which was arranged for Toronto under the auspices of Section K (Social and Economic Sciences). The engineering programme was unusually excellent in many ways. Arrangements for this were due to the very efficient work of Mr. J. B. Tyrrell, of Toronto, vice-president of Section M. The Society for the Promotion of Engineering Education met with Section M.

The social and economic sciences (Section K) had no separate programme, but through the enthusiastic and efficient work of Dr. F. G. Cottrell, of the U.S. National Research Council, a symposium on an international auxiliary language was arranged. This was held at a joint session on Friday afternoon of Sections K and Q (Education). The symposium was preceded by the address of the retiring vice-president of Section K, Dr. F. L. Hoffman, of the Prudential Life Insurance Co. of America, on "The Organisation of Knowledge."

A programme of great general and cultural interest was presented by the Committee on the History of Science in a session held on Thursday morning. Among others, Dr. J. P. McMurrich—afterwards elected president of the association for 1922—gave a paper on the artistic anatomical work of Leonardo da Vinci.

The extraordinary success of the meeting was due mainly to the tireless and varied activities of the members of the local committee under the chairmanship of Prof. J. C. Fields, who foresaw all needed arrangements and added many pleasant and convenient details. Especially was praise given to the very artistic official badge, which will serve as a worthy commemoration of one of the most satisfactory meetings of the association. The very onerous and pressing work of caring for the publication of the general programme was undertaken by Dr. J. P. McMurrich, who handled this very difficult and confusing complex of details with very great skill. The University of Toronto Press gave very efficient service in this connection.

Publicity was unusually well handled. The recently organised Science Service co-operated with the association in arousing public interest in the meeting through the daily press. Dr. E. E. Slosson, editor of Science Service, and Mr. Watson Davis were present throughout the meeting on behalf of Science Service. Besides the valuable publicity work of Science Service, which is under the control of the American Association, the U.S. National Academy, and the U.S. National Research Council, and which operates for the sole purpose of disseminating scientific knowledge through the newspapers, just as valuable and efficient publicity work was accomplished by the local Sub-Committee on Publicity, of which Prof. A. G. Huntsman was chairman.

At the council meeting of the association the sum of 4000 dollars was allocated in grants for research, according to the recommendations of the committee on grants. Prof. B. K. Emerson, of Amherst, Mass., and Prof. E. A. Smith, of the University of Alabama, were elected to emeritus life-membership on account of the Jane M. Smith Endowment Fund. On a vote by the council the president appointed the following committee to consider the subject of reciprocity between the United States and Canada so far as this concerns scientific work:—E. L. Nichols (chairman), F. D. Adams, T. C. Chamberlin, J. C. Fields, and J. C. Merriam. It was decided that the next annual meeting of the association should be held at Boston, Mass., on December 26–30, 1922, and the 1923–24 meeting at Cincinnati, Ohio, in December 1923.

Dr. J. P. McMurrich, professor of anatomy in the University of Toronto, was elected president of the association. The following vice-presidents of the several sections were elected:—A (Mathematics), G. A. Miller, University of Illinois; B (Physics), Frederick A. Saunders, Harvard University; C (Chemistry), W. Lash Miller, University of Toronto; D (Astronomy), Otto Klotz, Dominion Observatory, Ottawa, Ontario; E (Geology and Geography), Charles P. Berkey, Columbia University; F (Zoological Sciences), Maynard M. Metcalf, Oberlin College; G (Botany), Francis E. Lloyd, McGill University; I (Psychology), Raymond Dodge, Wesleyan University; K (Social and Economic Sciences), Henry S. Graves, Washington, D.C.; L (Historical and Philological Sciences), William A. Locy, Northwestern University; M (Engineering), George F. Swain, Harvard University; N (Medical Sciences), Francis W. Peabody, Harvard Medical School; and O (Agriculture), R. W. Thatcher, University of Minnesota.

BURTON E. LIVINGSTON.

The Use of Light as an Aid to Aerial Navigation.

AT the meeting of the Illuminating Engineering Society on January 31, Lt.-Col. L. F. Blandy, who is associated with the Air Ministry, delivered a paper on "The Use of Light as an Aid to Aerial Navigation." Gen. Sir Frederick Sykes, Controller-General of Civil Aviation, presided. In the introductory portion of the paper the author described the lighting of the passengers' accommodation and crew's quarters, etc., on a modern airship, the light being derived from electric lamps fed from a generator driven by the engine. Small candle-power lamps are used for illuminating the dials of instruments, etc., on some machines. The external lighting of aircraft has been closely studied by the International Air Convention, which has defined precisely the equipment of a forward white light of 8-km. range, a red light of at least 5-km. range on the left hand, and a green light of similar range on the right. Special arrangements must be made to prevent the green light being seen from the left side or the red light from the right. A white rear light is also provided.

In navigating the air, principles similar to those in use at sea are thus being adopted for external lights, but owing to the motions of aircraft and their high speed the arrangement of navigation lamps demands special care. The relative speed of approaching machines may attain 200 m.p.h., *i.e.* 3·3 miles per minute. From the time of sighting headlights to the moment of collision the time available may be only 90 seconds, and it looks as though the range of navigation lights may have to be increased. Lights used by aircraft to facilitate landing may be either chemical or electric. Gas-filled electric lamps of 1000–2000 c.p. have been developed for this purpose, and appear to have some advantages over flares, notably as regards ease of control and extinction at will. Aerodrome lighting includes lights used to define the positions of buildings and other obstruc-

tions, illumination of the actual ground, and fixed illuminated signs to show the position of wind, etc. At Croydon the lighting of high wireless masts, which form dangerous obstructions, has been effected by placing 1000-c.p. gas-filled lamps, screened red, on the top of the masts. These form a good recognition mark.

Ground illumination requires special care to avoid dazzling the eyes of pilots at some angles. A special arrangement recommended at the International Air Convention is the use of lights arranged in the form of two "L's" to indicate positions for "taking off" and landing. Such lights were originally mounted in reflectors covered by flat glass discs in such a way that they were readily visible from above, but invisible at close range. Better methods of diffusion, enabling lights to be seen at all angles, have since been devised. Searchlights appear helpful, but have to be used with care to avoid confusing shadows when the machine is near the ground. An appendix to the paper contains particulars of the recommendations of the International Air Convention in regard to signals of distress, etc. Much has yet to be done in this new field, but the paper affords a useful review of existing procedure.

The Preservation of Stone.

A LECTURE to the Royal Society of Arts on the above subject by Mr. Noel Heaton is published in the Journal of the society for December 30 last. The lecturer gave an account of the various attempts which have been made to solve the important problem of preventing the decay and disintegration of stonework in buildings. The great majority of modern stone buildings, and a still greater proportion of medieval buildings, are constructed of limestone or sandstone, and the problem centres around these varieties rather than about the more resistant granite, used only to a limited degree. The causes of disintegration may be natural, depending on fluctuations of temperature, on rain, on erosion by wind, and, in ferruginous sandstones, on oxidation. Minute differences in structure often cause great differences in durability. The growth of vegetation on stone usually hastens decay. The most potent cause of decay is, however, the "unnatural" action of sulphuric acid, derived from coal-smoke, coupled with the accumulation of soot and grime. Sir Frank Baines, who introduced the lecturer, stated that, roughly, 80,000 tons of sulphuric acid are thrown annually into the London atmosphere. Strain set up by the rusting of iron is also a contributory cause of decay. The lecturer then turned to the means of preventing decay.

An indirect method of preventing decay is to further, by every possible means, the campaign against atmospheric pollution. The stone may be treated with preservatives, which were divided into three groups: (*a*) those acting merely as surface coatings; (*b*) those impregnating the stone without chemical action; and (*c*) those operating by chemical reaction with the stone. In the first class are paint and limewash, the latter being useful where the stone is subjected to a moist atmosphere, but protected from rain. In the second class are mineral wax applied by heat or in solution in benzene, drying oils, creosote, or gelatinous precipitates formed on the stone. The first process is very old, and is effective for certain purposes. Treatment with alum solution, followed by soft soap, which results in the precipitation of an aluminium salt of the fatty acids, is recommended.

In the third class treatment with baryta is effective in repairing a stone disintegrated by sulphuric acid. A common method is the deposition of silica or silicates. Treatment with waterglass leads to unsightly efflorescence. This may be reduced by treating with a solution of arsenic acid after the waterglass, but the most satisfactory results are obtained with silicofluorides, introduced in France by Kessler in 1883. A solution of magnesium silicofluoride reacts with limestone:

$$MgSiF_6 + 2CaCO_3 = SiO_2 + MgF_2 + 2CaF_2 + 2CO_2.$$

The solution, known as "Fluate," is manufactured in France, and the lecturer stated that, although the results were conflicting, it appeared to be beneficial. In America the double salts of magnesium and zinc were preferred. The use of the solution has recently been investigated by Prof. Desch, in conjunction with the Department of Scientific and Industrial Research, and, although the detailed results have not yet been published, the conclusions appear to be that too strong a solution should not be used (not stronger than 10 per cent.), and that the mode of application should be adjusted to particular conditions. The method is most useful on new work. The use of nostrums of unknown composition is strongly condemned, as they may cause great injury. Sir Frank Baines also contributed some valuable information in the discussion on the lecture.

Mathematics in Japan.

A GOOD many years ago there was an exhibition at Earl's Court in which the Japanese Government and nation took a conspicuous part. For several reasons the Japanese art section was particularly interesting. It contained priceless and authentic specimens of their national painting and handicraft before they were influenced by foreign methods and ideals. Besides this, there were paintings by some of their modern artists who adopted Western methods and conventions. The contrast was very striking, and in some respects not very satisfactory.

Similar reflections are suggested by the present state of Japanese mathematics, as shown, for example, in various mathematical papers recently received from the University of Tokyo. Circumstances are different because mathematical science is now cosmopolitan, and no single nation can afford to neglect its various developments. At the same time, like nationality in drinks, there is a kind of nationality in science, art, or any other human activity, which is justifiable, and even instructive, if it is not carried to excess. We may notice it, for example, in the papers and treatises of the leading mathematicians, such as Klein and Dedekind on one hand and Poincaré, Hermite, and Darboux on the other. The elegance of the best French text-books is scarcely equalled, if at all, by those of any other nation; at the same time, the corresponding German works are distinguished by thoroughness, method, and fulness of references. The treatise on elliptic modular functions by Klein and Fricke and Poincaré's memoirs on Fuchsian functions illustrate the point.

It is difficult to be sure how far Japanese mathematics is entirely original. They had various approximations to π, some of which, at any rate, seem to have been of their own invention. They had an extraordinary gift for solving numerical equations of high degrees by approximation, and one Japanese writer appears to have anticipated many of Steiner's

theorems on poristic systems of circles. Besides this, they discussed elegant problems more or less suggested by familar objects, such as fans, toys, etc.

It would be a pity if all truly Japanese characteristics were to become obliterated. Apart from æsthetic considerations, if they avoid falling into the rut of Western methods there is a chance of their producing something really novel and suited to their genius. They might, for instance, solve some of the outstanding problems of group theory or make some notable advance in Diophantine analysis—a subject which seems to have lost its fascination for most European mathematicians.

The attitude of an individual towards foreign mathematics is sometimes peculiar, and even amazing. Not very long ago an English lady spending a holiday at Utrecht was introduced to an eminent Dutch mathematician. Having a mathematical friend in England, she asked the professor his opinion of English mathematicians. The answer was to the effect that their work was so strangely insular that he could not spare the time to make himself familiar with it. This was after Cayley, Sylvester, and Salmon had published much of their best work on invariant theory.

G. B. M.

University and Educational Intelligence.

CAMBRIDGE.—In connection with the meeting of the Royal Agricultural Society at Cambridge in the coming summer, honorary degrees are proposed for H.R.H. Prince Albert, the President of the Society, Mr. C. R. W. Adeane, Sir Gilbert Greenall, Sir A. Daniel Hall, Mr. E. S. Beaver, Mr. A. E. Humphries, Mr. Ernest Mathews, and Mr. G. P. Hawkins.

An open Fellowship, for which all graduates of the University are eligible who took their first degree not earlier than June 1919, is announced by King's College. Any one who wishes to offer himself as a candidate should communicate with the Provost as early as possible.

LEEDS.—Prof. Sir Berkeley Moynihan has given to the University an endowment for the annual award at the Leeds Medical School of a gold medal to the best student of the year in Medicine and Surgery. In accordance with Sir Berkeley Moynihan's wish the gold medal will bear the name of William Hey in commemoration of the work of that great Leeds surgeon. The Council of the University in accepting the endowment have recorded their thanks to Sir Berkeley Moynihan for his generous gift. William Hey (1736–1819) was one of the pioneers of modern surgery. A brilliant operator and teacher, he established the tradition of surgical skill which has ever since been one of the chief distinctions of Leeds. He was a friend of Joseph Priestley when the latter was Minister of Mill Hill.

LONDON.—The following course of free public lectures is announced: At King's College, Strand, at 5.15 on Wednesdays, March 8, 15, and 22, "The Quantum Theory of Radiation and the Constitution of the Atom," Prof. Nils Bohr (in English)

THE bearing of improved means and methods of education receives striking confirmation in the figures adduced by Mr. Percival Sharp in his address in January at the annual meeting of the Association of the Directors and Secretaries for Education held in the County Hall, London. Dr. Sharp submitted official statistics for England and Wales showing the curve of crime from 1870, when the population of England and Wales was 22,000,000, down to 1919, when it had reached nearly 37,000,000. In 1870 107,621 men and 39,604 women above sixteen years of age—a total of more than 147,000 persons—were committed to prison. In 1919 the numbers fell to 22,289 men and 8718 women—a striking difference, having regard to the great increase in population. There are no figures available earlier than 1893 concerning indictable offences tried at the Quarter Sessions. The number of men convicted shrank in 1919 to 5200, as compared with 8200 in 1893, whilst the number of women convicted declined from 1245 in 1903 to 826 in 1919. The number of men tried summarily for indictable offences fell from 20,000 in 1893 to 16,000 in 1919, and of women from 5000 to 3900. The figures for non-indictable offences fell from 133,000 to 73,700 for men in the same years, and from 43,000 to 18,000 for women. The Home Office has decided to close eight prisons and to shut down the female wings of six other prisons at the end of March next. So far as a great industrial and commercial area like Manchester is concerned, two large industrial and reformatory schools have recently been closed, and the returns available show that between 1907 and 1921 the number of children under maintenance shrank from 659 in 1909 to 209 in 1921. These figures are conclusive as to the value and influence of education in the training of the children of the nation, and condemnatory of any proposed legislative measures of economy with regard to the restriction of such training. Rather they enforce the necessity for continued development and improvement.

A LIST of students from the King's Dominions overseas and from foreign countries studying in the universities and university colleges of the United Kingdom has been compiled by the Universities Bureau of the British Empire. The following figures gleaned from the list are of general interest, which would, however, be greatly enhanced if to them could be added statistics of the very numerous students from abroad who are studying at the Inns of Court, in other professional and technical institutions not included in universities and university colleges, and privately:—Of the total number, 4470, Asia contributed over a third (1576), Africa 1187, America 781, Europe 645, and the Pacific, 281. Of the Asiatics 1240 are from India, Burma, and Ceylon; this includes 446 at London, 173 at Edinburgh, 171 at Cambridge, 170 at Oxford, and 65 at Glasgow. The Indian Students' Department of the Office of the High Commissioner in 1921 estimated that there were 1500 Indian students at the universities and technical colleges and 600 at the Inns of Court. From China came 143, of whom 49 are at London, 25 at Edinburgh, and 17 at Cambridge. Of 73 from Japan 55 are at London. South Africans and Rhodesians number 832, including 327 at London, 178 at Edinburgh, 95 at Dublin, 82 at Oxford, and 42 at Cambridge. Of 294 from Egypt, 88 are at London and 52 at Birmingham. The U.S.A. contributed 400, of whom 210 are at Oxford, a large proportion being Rhodes scholars. Of 200 from Canada, 87 are at Oxford. South America contributed 75 and the West Indies 101, of whom 33 are at London and 23 at Edinburgh. Of the Europeans, 91 are from Russia, 61 from Switzerland, 62 from France, 52 from Greece, 70 from Scandinavian countries, 49 from Rumania, and 48 from the kingdom of the Serbs, Croats, and Slovenes. Of 178 Australians, 50 are at Oxford, 41 at London, 36 at Edinburgh, and 35 at Cambridge; while of 102 New Zealanders, 27 are at London, 25 at Edinburgh, 24 at Cambridge, and 20 at Oxford.

Calendar of Industrial Pioneers.

March 2, 1892. Sir John Coode died.—A pupil of J. M. Rendel, Coode became resident engineer, and then engineer-in-chief, of the Portland breakwater, completed in 1872, and afterwards rose to be the most distinguished harbour engineer of his time. Among his greatest works were those at Cape Town, Fremantle, and Colombo. From 1889 to 1891 he served as president of the Institution of Civil Engineers.

March 3, 1895. Alfred Giles died. March 4, 1847. Francis Giles died.—Both the Giles, father and son, were successful civil engineers. Francis Giles was employed under Rennie, and later carried out various important harbour and canal works; while his son was largely concerned with railway projects in Denmark, France, Canada, Galicia, and other countries. In 1893 Alfred Giles was president of the Institution of Civil Engineers.

March 4, 1902. Bryan Donkin died.—The grandson of Bryan Donkin (1768–1855), known for his pioneering work in paper-making machinery, Donkin succeeded to the business founded by his grandfather. He was, however, best known for his study of thermodynamics and the scientific testing of steam engines, his investigation of steam jacketing and condensation, and his work on gas and oil engines.

March 6, 1900. Gottlieb Daimler died.—A native of Würtemberg, Daimler became a practical engineer, worked in England under Whitworth, and about 1870 became associated with the gas-engine pioneer Nicolas Otto. In the 'eighties he constructed small internal-combustion engines, one of which he fitted to a bicycle, and in 1890 he founded the Daimler Motorengesellschaft at Cannstadt, where he died.

March 7, 1809. François Blanchard died.—One of the most celebrated of the early aeronauts and a reputed inventor of the parachute, Blanchard made some sixty ascents. On January 7, 1785, with Dr. John Jeffries, he was the first to cross the Channel in a balloon. His wife, Sophie Armant, was also an intrepid aeronaut, and perished in a balloon accident in 1819.

March 8, 1803. Francis Egerton, Duke of Bridgewater, died.—The Duke of Bridgewater has been called the founder of British inland navigation. Succeeding to the family estates at an early age, he settled in Lancashire, and to develop his collieries engaged Brindley to construct the canal from Worsley to Manchester and that from Manchester to the Mersey, the first English canals.

March 8, 1887. James Buchanan Eads died.—Born in Indiana in 1820, Eads's whole life was bound up with the Mississippi. He made a fortune by raising steamboats sunk in the river, achieved a great reputation during the Civil War by the rapid construction of gunboats for its defence, in 1867–74 constructed the great steel arch bridge which spans it at St. Louis, and later originated the jetties at its mouth for improving the channel. He was the first American to be awarded the Albert medal of the Royal Society of Arts.

March 8, 1889. John Ericsson died.—A fertile inventor, a noted engineer, and one of the foremost constructors of warships, Ericsson was a native of Sweden. From 1826 to 1839 he was in England, where he produced the first steam fire-engine, constructed the locomotive "Novelty," and built the screw-driven vessel *Robert F. Stockton*. The remainder of his life was spent in America, where during the Civil War he inaugurated the era of the armoured turret battleship. The great fight between Ericsson's *Monitor* and the *Merrimac* took place on March 9, 1862.

E. C. S.

Societies and Academies.

LONDON.

Royal Society, February 23.—Sir Charles Sherrington, president, in the chair.—C. D. **Ellis**: β-Ray spectra and their meaning. A method of finding the wave-lengths of γ-rays of too high a frequency to be measured by the crystal method depends on the fact that γ-rays are converted into β-rays according to the quantum relation. If the energies of the groups of electrons ejected by γ-rays be added to the work done in removing the electron from inside the atom to the surface, $h\nu$ is obtained. The work is found from observations of the energies of corresponding groups excited in different substances, and the method is applied to find the wave-lengths of the γ-rays emitted by radium B, radium C, and thorium D. The energies of the β-ray groups of thorium D have been measured for this purpose. The γ-rays are emitted from the nucleus and the numerical values of the wave-lengths suggest that the quantum dynamics applies to the nucleus and that part of the structure can be expressed in terms of stationary states. Suggestions for the energy of these stationary states in radium B and thorium D nuclei are given.—A. E. **Conrady**: A study of the balance. The first weighings by the Gaussian method of exchange made with an inexpensive analytical balance gave a probable error of only 0·004 mg. A constructional fault in the suspensions was remedied and the probable error fell to 0·0013 mg. A further systematic error, depending on the sequence of pointer readings in successive exchanges was attributed to imperfect elasticity and irregular curvature of knife-edges. A method of double exchange of loads which, by close adjustment of a light rider, caused all readings to fall on two alternating positions of rest, brought the probable error to 0·0008 mg., and it seemed now largely due to irregular air-currents. Arrangements allowing manipulation of loads without opening of balance case reduced the probable error to an average value of 0·0004 mg. If the centre of gravity of the moving parts falls in the supporting line of the central knife-edge ("autostatic" state), the reading of the pointer becomes independent of levelling of the balance case, and highly accurate results can be obtained on very infirm supports.—J. S. **Owens**: Suspended impurity in the air. The essential part of a new instrument for measuring impurities is a fine jet of air which strikes a glass surface with high velocity, depositing its dust thereon. The velocity of jet affects the operation of the instrument. The adhesion of dust to the glass has suggested applications which indicated (*a*) that visibility is usually a function of amount of suspended impurity; (*b*) that suspended dust travels over great distances; records being described of dust from the Continent; (*c*) that the microscopical examination of such records indicates differences depending upon wind direction.—R. V. **Southwell**: On the free transverse vibrations of a uniform circular disc clamped at its centre; and on the effects of rotation. An analysis of the influence of rotation upon the normal modes and frequencies of free transverse vibration in a uniform circular disc, complete freedom from constraint being assumed, is extended to cover the effects of constraints which prevent, along a small circle concentric with the free edge, the occurrence either of finite transverse displacement w, or of finite slope $\delta w/\delta r$. The constraints are assumed to have no effect upon the centrifugal stress-system. Clamping a non-rotating disc along a small circle produces only slight changes of frequency in modes characterised by two or more

nodal diameters, but is important in its effect on the "symmetrical" modes and on modes having one nodal diameter. In the other extreme case, when the flexural rigidity may be neglected, the central constraint has no effect upon the natural frequencies. In the general case, in which both flexural and centrifugal stresses are considered, the gravest frequencies in modes which have nodal diameters may be calculated by the formula previously given; a special investigation is made of the gravest frequency in a symmetrical mode.—A. E. **Oxley**: Magnetism and atomic structure. II.—The constitution of the hydrogen-palladium system and other similar systems. The susceptibility of palladium black charged with hydrogen is less than that of pure palladium black. From this it is concluded that the occluded hydrogen is neither in the atomic nor molecular state. The results agree with the existence of a chemical compound, probably Pd-H. In the hydrogen molecule, each atom thrusts its electron into the other atom, the bond being represented by a pair of electrons held in common. The palladium atom has 46 electrons, the hydrogen atom 1 electron, the latter being thrust into the outer shell of the palladium atom. If these 47 electrons take up a configuration like that of the silver atom (atomic number 47), which is diamagnetic, the fall of susceptibility may be accounted for. Paramagnetic manganese fused in hydrogen becomes ferro-magnetic. The occluded hydrogen atoms probably thrust their electrons into the outer shells of the manganese atoms, producing in them electron configurations analogous to that of the iron atom.—T. **Carleman** and G. H. **Hardy**: Fourier's series and analytic functions. If $f(\lambda)$ is integrable in the interval $(0, 2\pi)$, and the associated function $\phi(u) = \frac{1}{2}\{f(a+u)+f(a-u)\}$, where $0<a<2\pi$, is harmonic and bounded in a certain neighbourhood of $u=0$, then the necessary and sufficient condition for the convergence of the Fourier series of $f(\lambda)$, at $\lambda=a$, is that $\phi(u)$ should tend to a limit when u tends to zero through positive values.—A. **McAulay**: Multenions and differential invariants. Pts. II. and III. The quadratic form is introduced: all multenion formulae may be put into invariant form. Tests, both by finite and by infinitesimal transformation, are given, for ascertaining whether invariance of each one of six types subsists for any given function. Multenion methods are compared with those of the Theory of Tensors and details are furnished for translating from one mode of presentation to the other. Pt. III. is a general survey of the applications of a Riemann manifold to relativity. In relation to matter and gravitation no new principle is introduced but the electro-magnetic field is treated in a novel manner. The scalar and vector potentials are wholly ignored. The application to matter in bulk is kept in mind, and it is considered imperatively necessary to adapt relativity methods to a sufficiently general set of relations as at least to leave Maxwell's explanation of crystalline reflection, refraction, and transmission of light intact.

Linnean Society, February 16.—Dr. A. Smith Woodward, president, in the chair.—R. R. **Gates**: The inheritance of flower size in plants. Reciprocal crosses were made between *Œnothera rubricalyx* and *Œ. biennis*, with petals 40 mm. and 20 mm. in length respectively. The size of flowers in F_1 was intermediate and relatively uniform. In F_2 there was a marked difference in size of flowers (*a*) on different plants, (*b*) in different flowers of the same plant, and (*c*) sometimes in the different petals of a flower. Measurements on F_3 and F_4 plants show that the hypothesis of several Mendelian factors for length of petal is an insufficient explanation. Variation curves show a tendency to segregation in flower-size between different plants, but also a tendency for the occurrence of smaller flowers, some petals being only 7 mm. in length. Segregation is therefore not confined to germ-cell formation, and is not Mendelian. Probably cytoplasmic differences are involved in this type of inheritance and variation.—W. **Dallimore**: The effect produced by wind at Llandudno. Wind causes remarkable dwarfing of trees and shrubs on the exposed rocks of the Great Orme's Head.—J. L. **North**: The possible successful growth of *Glycine Soja*, Sieb. & Zucc., as a profitable crop in Great Britain. The flattening of the branches, the result of close sowing—the Chinese method—is retained even when plants are grown wide apart. Also if a plant starts at a wrong angle it twists itself upon its base to bring it into line with the other plants. By using the earliest ripening seeds of the previous year of a so-called German acclimatised plant earlier maturity has been obtained. Plants in 1914 ripened on November 28, while last year they reached a corresponding degree of ripeness early in September.

Royal Microscopical Society, February 15.—Prof. F. C. Cheshire, president, in the chair.—A. L. **Booth**: The microstructure of coal from an industrial standpoint. Microstructure can be applied to augment chemical analysis in fuel selection. Thin sections of bituminous coals can be classified as humic, spore, and cannel. These are arbitrary standards, thus the use of the microscope in industrial coal problems is purely empirical. For selection purposes an unknown coal is compared with coals of known properties. Little is known of the influence of the various coal constituents on the properties of coal. Chemical analysis does not necessarily give information as to the coal type. Much published work on coal lacks the essential common factor, the microanalyses, whereby the whole can be correlated.

CAMBRIDGE.

Philosophical Society, February 6.—Prof. A. C. Seward, president, in the chair.—H. Hamshaw **Thomas**: On some new and rare Jurassic plants from Yorkshire (V): Fertile specimens of *Dictyophyllum rugosum* L. and H. *Dictyophyllum rugosum* has been known since 1828 and its sporangia have now been found near Scarborough. They are similar to those of the modern ferns Cheiropleuria and Platycerium and confirm the suggested relationship to the Dipterineae.—F. A. **Potts**: On the food of Teredo, the shipworm. The Teredinidae are invariably found burrowing in wood. The minute fragments excavated by the rotating shells pass through the alimentary canal and are in part digested by it. The stomach has an enormous coecum which retains quantities of wood, but digestion takes place in the so-called "liver," some of the cells of which are gorged with particles of wood. In living tissue their amoeboid pseudopodia are active and many of the cells are detached and float freely in the lumen. There are no commensal organisms assisting in wood digestion and it seems unlikely that plankton forms play any significant part in the nutrition of these molluscs.—E. H. **Neville**: The definition of an envelope.

MANCHESTER.

Literary and Philosophical Society, November 29, 1921.—Mr. T. A. Coward, president, in the chair.—F. T. **Peirce**: Electromagnetic valency and the radiation hypothesis. A magnetic doublet, consisting of two electrons in small orbits (ring or vortical electrons), furnishes a probable physical basis for a

radiation hypothesis of chemical reactivity, and suggests the following results for non-electrolytes:— The bond can be broken only by radiation of definite frequency ν, the most intense impact resulting only in ionisation. External illumination as a criterion should be large for unimolecular decomposition or transformation, considerable for reversible reactions, especially the effect due to the radiation exciting the endothermic process, and inappreciable for irreversible combination. Corresponding frequencies are selectively absorbed or emitted. The energy change is double, corresponding to the attainment of the critical unstable equilibrium and of the normal stable state. For the complete change in intrinsic energy U, $-U = nH(\nu - \nu')$ per mol. The system can accumulate absorbed radiant energy up to a limit of one quantum per electron. It emits in quanta, but absorbs and scatters continuously. The frequencies and energy changes are altered by solvents, but not by intermediate compounds.

December 13, 1921.—Mr. T. A. Coward, president, in the chair.—Laura E. **Start**: Sea Dayak fabrics and their decoration. The patterns of part of the group of Iban cloths collected during the Cambridge Expedition to the East Indian Archipelago in 1899 are traditional. They are symbolical, and in some cases designate the rank or tribe of the wearer. Anthropomorphs, zoomorphs, and phyllomorphs form the chief motives, and of these the animal patterns predominate. For the origin of the life-history of patterns, in which man, the frog, the crocodile, the shrew, and the tiger are used symbolically, we must go back to the Proto-Malay stock, from which the Iban probably sprang, or consider the patterns a development due to the Ibans themselves.

January 6.—Joint Meeting with the Manchester Sections of the Society of Chemical Industry, the Institute of Chemistry, and the Society of Dyers and Colourists.—Dr. Edward Ardern in the chair.—A. **Harden**: Biochemical method. The methods and the difficulties of obtaining trustworthy results in biochemical research are due to the many factors which involve the living organisms. The occurrence of vitamins in foodstuffs, the differences between the various kinds of vitamins, the serious effects of ill-chosen diet for children, and the destruction of vitamins by heat and contact with air were discussed.

Society of Glass Technology, February 15.—The president, Dr. M. W. Travers, in the chair.—F. W. **Hodkin** and W. E. S. **Turner**: The relative advantages and disadvantages of limestone, burnt lime, and slaked lime as constituents of common glass batches containing soda ash and saltcake. Pt. II. The rates of melting depend upon the form of alkali and lime used as well as the relative amounts of lime and soda used. In the case of glass such as that used for bottles made on automatic machines, and containing about 8 per cent. of lime, the soda ash burnt lime batch appeared to be the most readily melted. With lime-containing glasses, the melting is assisted by the addition of small amounts of other oxides, particularly of magnesia. In the case of glasses containing about 12 per cent. of lime, the slaked lime containing batches generally melted most readily. A discussion followed the paper, and the remainder of the meeting was taken up with a debate on the subject of "The Melting of Glass." A number of questions on the subject had been submitted by members, and formed the basis of the discussion; this being continued from the Leeds meeting in November 1921, at the general request of members.

Diary of Societies.

MONDAY, MARCH 6.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.—General Meeting.

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting), at 7.—E. Ambrose and others: Discussion on E.H.T. Cable-testing.

ARISTOTELIAN SOCIETY (at University of London Club, 21 Gower Street, W.C.1), at 8.—S. N. Dasgupta: The Logic of the Vedanta.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—Special and Business Meetings.

ROYAL SOCIETY OF ARTS, at 8.—Prof. A. F. C. Pollard: The Mechanical Design of Scientific Instruments (3).

SOCIETY OF CHEMICAL INDUSTRY (at Chemical Society), at 8.

SURVEYORS' INSTITUTION, at 8.—B. P. Davies: The Analysis of Building Costs.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—C. E. N. Bromehead: The Influence of its Geography on the Development of London.

SOCIETY OF CHEMICAL INDUSTRY (London Section) (at Chemical Society), at 8.—W. Cullen: Gold Metallurgy of the Witwatersrand, Transvaal.

TUESDAY, MARCH 7.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Arthur Keith: Anthropological Problems of the British Empire. Series I.—Racial Problems in Asia and Australasia (3).

ROYAL SOCIETY OF ARTS (Dominions and Colonies Section), at 4.30.—Major Sir Humphrey Leggett: Tanganyika Territory (formerly German East Africa).

ANGLO-SWEDISH SOCIETY (at Swedish Hall, Harcourt Street, W.1), at 5.30.—Dr. F. A. Bather: The Sea-lilies of Gotland and Dudley.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—N. S. Lucas: Report on the Deaths which occurred in the Society's Gardens during 1921.—F. Balfour Browne: The Life-history of the Water-Beetle *Pelobius tardus* Herbst.—Dr. R. Broom: The Temporal Arches of the Reptilia.—F. W. Urich, Dr. H. Scott, and Dr. J. Waterston: Note on the Bat-Parasite *Cyclopodia greeffi*, and on a new Species of Hymenopterous (Chalcid) Parasite bred from it.—S. K. Montgomery: Direct Development in a Dromiid Crab.

INSTITUTION OF CIVIL ENGINEERS, at 6.—A. C. Walsh and W. F. Stanton: The Improvement of the Port of Valparaiso.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (Technical Meeting), at 7. H. W. Lee: A Chart for finding the Depth of Focus of a Lens.—H. Farmer: Direct Photography: a fully efficient alternative and addition to our present system.

RÖNTGEN SOCIETY (at Institution of Electrical Engineers), at 8.15.—L. H. Clark and B. D. Watters: Comparisons between the Therapeutic, Photographic and Ionisation Effects of Ultra-Violet and of Beta Radiation.—E. E. Burnside: Apparatus for deep X-ray Therapy.

WEDNESDAY, MARCH 8.

INSTITUTE OF METALS (at Institution of Mechanical Engineers), at 10 A.M.—Dr. G. D. Bengough: Notes on the Corrosion and Protection of Condenser Tubes.—At 2.30.—F. Adcock: The Internal Mechanism of Cold-Work and Recrystallization in Cupro-Nickel.—Research Staff of the General Electric Company: The Effect of Impurities on Recrystallization and Grain Growth.—Dr. H. Moore and S. Beckinsale: Further Studies in Season-Cracking and its Prevention. Condenser Tubes.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Baron F. Nopsca: The Geological Importance of the Atavistic Reptilian Fauna of the Upper Cretaceous of Transylvania.

ROYAL SOCIETY OF ARTS, at 8.—W. A. Appleton: The Proper Functions of Trade Unions.

INSTITUTION OF AUTOMOBILE ENGINEERS (at Institution of Mechanical Engineers), at 8.—A. A. Remington: The Design and Function of Laminated Automobile Suspension Springs.

THURSDAY, MARCH 9.

INSTITUTE OF METALS (at Institution of Mechanical Engineers), at 10 A.M.—Prof. C. A. Edwards and A. J. Murphy: The Rate of Combination of Copper and Phosphorus at Various Temperatures.—Dr. W. Rosenhain: Some Cases of Failure in "Aluminium" Alloys.—Prof. F. C. Thompson and E. Whitehead: Some Mechanical Properties of the Nickel-Silvers.—Dr. D. Hanson and Marie L. V. Gayler: A Further Study of the Alloys of Aluminium and Zinc.—A. Westwood: The Assay of Gold Bullion.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. H. M. Lefroy: The Menace of the Insect Pest: The Balance of Life in Relation to Insect Pest Control (2).

ROYAL SOCIETY, at 4.30.—Prof. T. R. Merton and S. Barratt: The Spectrum of Hydrogen (Bakerian Lecture).

LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5. —W. H. Young: The Theory of Functions of Two Complex Variables. —Col. R. L. Hippisley: The Nodes of the Three Bar Sextic.—R. F. Whitehead: The Number of Solutions in Positive Integers of the Equation $yz+zx+xy=n$.—T. Stuart: The Determination of the Criterion to prevent "Hunting" in Hartnell's Governor.—N. Wiener: The Average Value of a Functional.—Lt.-Col. A. Cunningham: On Least Primitive Roots.

ROYAL COLLEGE OF PHYSICIANS, at 5.—Dr. M. Greenwood: The Influence of Industrial Employment on General Health (Milroy Lectures) (1).

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Miss Coombs, Mrs. Bottrill, and others: Discussion on the Family Group System in Infant Schools.

OPTICAL SOCIETY (at Imperial College of Science and Technology), at 7.30.—T. Smith and J. S. Anderson: A Criticism of the Nodal Slide as an Aid in Testing Photographic Lenses.—A. J. Bull: A Non-polarising Spectrophotometer.—J. Guild: The Photometry of Optical Instruments.—T. Smith: A Projective Treatment of the Submarine Periscope.—A. J. Awards for Discovery and Invention.

AN example of the changed conditions brought about by the policy of Government encouraging the application of science to industry will be found in the "Report of the Inter-Departmental Committee appointed to consider the Methods of dealing with Inventions made by Workers aided or maintained from Public Funds" (pp. 25, H.M.S.O., price 6*d*. net). Before the War this subject was dealt with by Departments in a manner which frequently caused workers to desire arbitrators who, if not more sympathetic, might at least have knowledge of affairs, and act in accordance with some guiding principles. There were three courses which might be adopted by Government Departments, involving complete control, control by Government with delegation of its rights to its contractors but leaving commercial use to the inventor, and finally release from any obligation, with freedom to deal with invention as the inventor pleased. In those days, however, the cases coming up for decision were few, and the number of individuals affected small, whereas now Government employs a large body of persons on scientific and technical work, any of whom may, at any time, produce an invention. The importance of such an invention, although emanating from a laboratory belonging to the Fighting Services, may be even greater from a civil than from a military point of view.

Urgency was imported into the consideration of the question when inventions of commercial value began to be produced by the Department of Scientific and Industrial Research. Regulations had already been framed by that Department by which, while the results of an assisted worker who has chosen some field for extending knowledge, are under no restriction as to publication, an obligation was imposed on him to consult the Department if he desired to make commercial use of his investigations. A patent might then be taken out in the joint names of the inventor and of an Imperial Trust, and the proportional interests of the Department, of the inventor, and of any co-operating bodies were determined by the Department. The inventor assigned all rights in the patent to the Imperial Trust, which it is understood found a difficulty in exploiting patented inventions commercially. Variation in treatment of the subject and the unsatisfactory nature of some of the prevailing conditions thus called for a settlement of the method of treating inventors aided or maintained from public funds, and of the method of utilising their inventions in industry.

The Report proceeds to consider the difficult subject of the ownership of inventions made in Government employment. It deals first with the case of research workers, and secondly with persons not specially employed on research, expressing the view that in connection with such questions as rewards and the enjoyment of commercial rights each case should be decided on its merits. It is clear from the context that, as regards inventions made by research workers, divergent views have been expressed by the numerous witnesses who have been called before the Committee, and the result of a consideration of these views is embodied in the following passage:—

"In the case of a research worker employed by Government, the view has been expressed that, since he is employed for the purpose of making investigations and is provided with equipment, accommodation and other facilities at the cost of the State, he should not, as a general rule, be entitled to a reward or to any rights in any invention made in the course of his duty. On the other hand, there is a feeling amongst scientific men that rewards for specially meritorious work would have the effect of encouraging further effort. While we are, on the whole, in agreement with the former view, we consider that these are questions which should be decided in the light of all the circumstances in each case, the general principle being that the invention is the property of the State, and that the reward to the inventor (either by way of a money grant or of a share of patent rights or otherwise) should be increased or diminished in proportion to the remoteness or proximity of the invention to the work for which he was engaged or for which he had special facilities or knowledge as the result of his employment."

From this statement it is apparent that the Committee appreciates that it would be unwise to lay down a rule governing all cases, and that in dealing with the question of rewards the merits of each individual case should be taken into consideration. To bring the matter to an issue certain principles are enunciated, the chief features of which are that a competent authority should define in the light of all the circum-

stances of the case the respective rights of the Government and of the inventor, and decide any reward to which he may be entitled; that where the rights in an invention capable of commercial exploitation belong to the Government, it should be exploited commercially for the benefit of the Government; and that the system of dealing with these matters should be uniform for all Government departments.

The mechanism for dealing with these matters is next sketched, and from the preceding argument it clearly has to take the form of a central organisation for all Departments of State. Accordingly it is recommended to set up an Inter-Departmental Patents Board having two main functions, one on the lines of the Royal Commission on Awards to Inventors, for the purpose of dealing with awards, deciding as to the extent of the assistance due to the inventor's position in a Department, and determining the share of the Government in commercial profits, and the other to arrange for the exploitation of patents to the best advantage. The Board itself would fulfil the former function by acting as an Awards Committee, but for the latter, which deals with commercial matters, it would establish an independent Exploitation Committee with its secretary as intermediary.

In order to secure the full confidence of the inventor, it is recommended that the Inter-Departmental Patents Board should be a neutral and impartial body, on which are to be found neither representatives of the Departments concerned nor of the technical workers, but that it should have a permanent chairman of sound legal training and experience, and members characterised by their knowledge of the application of research and invention to industry. As this aspect of the work of the Board is judicial, it is deemed well to keep separate from the commercial aspect, which would be delegated to a committee of a different type—the Exploitation Committee—composed of nominees of the Departments, of the Treasury, and of business men with suitable experience and willing to assist in the exploitation of patents.

The Report proceeds to consider more closely the proposed mode of working of the Inter-Departmental Patents Board, this Board sitting as an Awards Committee, and of the Exploitation Committee. The Inter-Departmental Patents Board would have a permanent Chairman, and a small staff, under the Chairman's direction, would co-ordinate the work of the two Committees. Its cost would be borne by the Treasury, part of whose functions it would have delegated to it; its awards, however, would not be subject to revision by the Treasury on the ground of amount, but only on questions of principle. An inventor would, in the first place, be deemed to hold in trust on behalf of the Government all rights relating to his invention, but would be entitled to obtain from the Board a decision defining his rights, and he would undertake to assign his patent if called upon to do so, or the Board might decide to leave the completion of the patent to the inventor for his sole benefit. All non-secret patents in which the State has an owning interest would be assigned, not as at present to a Secretary of State, or to a Departmental Trust, but to a single organisation. The Board would also consider the case of the Government servant who was not specially engaged on research or development work, but who produced an invention.

The Awards Committee would consider the rights of the inventor in the light of the principles enunciated above. Except only in respect to awards would this Committee or the Board itself deal with secret patents for which the inventor has no possibility of securing commercial rights and the use of which is limited. Decisions as to maintaining their secrecy must remain in the hands of the respective Departments, who, if they desired, could consult in private with the Board. To avoid an undue burden being thrown upon the Inter-Departmental Board, it is provided that the Departmental Awards Committee of any Department should act as a committee of the Main Board and have power to deal with minor cases, forwarding to the Main Board only such cases as appear important as involving principles, or as being likely to result in an award exceeding 1000*l*.

Indications are given in the Report as to the mode of treatment by the Awards Committee of inventions which are a result of work by a team of part-time workers, and by workers aided by grants given for the sole purpose of increasing the bounds of knowledge.

The work of the Exploitation Committee is a matter of peculiar difficulty, seeing that this Committee would have to advise as to the advantage of completing protection by patents and exploiting them commercially when patented, and arrange with their business agents for placing them in the most favourable manner. It is hoped from experience during the War that men engaged in industry and commerce would still be willing to place their services at the disposal of the State for the achievement of these national aims. It would be the duty of this Committee to secure profits from the useful application of the patents under its charge, whether from their sale or from licences for their use. It would have the power of making a final decision, as this is vital in order that business dealings may be brought to an issue quickly and satisfactorily, and would employ sales agents paid on commission. If demonstrations on the semi-industrial scale, or works trials on the large scale, appeared desirable, this Committee would be empowered to carry them out. The

Exploitation Committee would also advise on the taking out of foreign patents, to be sold outright, however, so as to avoid the inconvenience of a Government organisation having to maintain a question of validity in a foreign country.

Some other matters of interest in this Report may be briefly mentioned. Doubt is expressed as to the soundness of the practice obtaining in one Department at least, of stopping short at provisional protection in the case of inventions of value for the preservation of health or of life, or the general use of which could be enforced by a Government Department; completion of the patent is now advised on the ground that very often no commercial use can be made of an invention unless a definite monopoly is granted to a manufacturing firm. Similarly, foreign patents for such inventions should be taken out.

For the encouragement of meritorious research workers, it is recommended in the Report that the head of a department should be given the power to promote successful investigators, or to secure for them special increases of salary, within certain limits, and without promotion out of their grade. The opinion is also recorded that the remuneration of scientific workers should be adequate and that they should have reasonable security of tenure.

While the Committee states it has not found that Government Departments are more reluctant than industrial firms to allow the publication of the results of scientific investigations, it is strongly of opinion that no obstacle should be placed in the way of research workers who wish to publish such results, regard being had to the national interest, and it proceeds to point out that the Government will secure the services of men of scientific ability and reputation, only if such permission is not withheld except under exceptional circumstances.

A mode of procedure is recommended to secure for the worker the opportunity of lodging a provisional application at the Patent Office without submitting it through his superior officer, who would, however, be supplied with a copy from the perusal of which he could decide as to whether the invention should be regarded as secret. Attention is directed to the importance of advertising to all concerned the conditions in force regarding the taking out of patents.

Such are the main features of this important Report. It cannot be denied that there existed an urgent need for a detailed consideration of the whole patent question for which different Departments of State had varying provisions and regulations. The matter is one of peculiar difficulty, on account of the personal association of a worker with the idea which ultimately leads to a successful patented process, while at the same time he is in receipt of maintenance and facilities. In spite of one phrase in this Report where the position of Government servants not specially engaged on experimental work is being discussed, in the words that "it was no part of the bargain made between them and the Government Department concerned when they entered into its employment, that they should make discoveries or inventions," it can safely be said that no such contract of service could reasonably be demanded. By maintaining a well-equipped establishment with adequate facilities and conditions for a well-chosen investigating staff, the employer has a good ground for belief that an atmosphere will be created in which at any time striking new ideas may arise, but he cannot claim to expect more than this in the way of striking developments. It is to this balance of interests that the Committee has applied itself, and in the passage quoted earlier in this notice has defined the position of research worker maintained by the Government, with regard to his claim to ownership in inventions. While laying stress on the general principles that the invention of such a worker is the property of the State, and that the reward to the inventor is contingent on the connexion of the invention with the work for which he was engaged, the Report makes clear that in settling the question all the circumstances of the case will be taken into account, having in mind, no doubt, such matters as the case when a Department desires to keep the invention secret, the merit and importance of the invention, together with any peculiarity in conditions of employment.

The tribunal suggested to adjudicate on such points, in view of its neutral character, should go far towards securing the confidence of the inventor, more especially as he should no longer be able to point to lack of uniformity in treatment by different branches of the Service. From the body of decisions of this tribunal there will, no doubt, gradually emerge sufficiently definite guiding principles to enable new applications to be dealt with expeditiously and fairly.

Much will depend on the interpretation of the principles described above in the first decisions arrived at by the Patents Board, and the extent to which encouragement to the scientific worker, one of the objects laid down in the terms of reference, is to result will be watched with interest.

Up to this point the Report is fairly clear, and there is no reason why its recommendations should not be carried out satisfactorily. It is to be hoped that it will be equally successful in the much more difficult task of exploiting inventions. Although, under the existing system in some Departments, a Government servant may be able to obtain permission to have reassigned to him the non-Governmental rights of an

invention made in the course of his work in order to exploit it commercially, he is rarely in a position adequately to carry this through, either from want of time on account of his normal duties, or from want of business ability. The inventor had the alternative in the event of a process proving an important one either to leave the Government Service and devote himself to his patent, or to remain in the Service and see the success of his invention jeopardised in its civil applications. The exploitation of Government-owned inventions by business men who have had experience in work of this kind is the only other way out of the difficulty that can readily be seen, and it is to be hoped that the confidence of the Committee will be justified by suitable public-spirited men coming forward to take up the work.

The Report bears internal evidence of much thought and consideration of diverse opinions, and thanks are due to members of the Committee for their hopeful effort to suggest an organisation which, by settling claims and disputes definitely and rapidly, will thereby remove an impediment to progress in investigation and at the same time afford the worker the opportunity of stating his case.

Principles and Problems of Aeronautics.

The Mechanical Principles of the Aeroplane. By Dr. S. Brodetsky. Pp. vii + 272. (London: J. and A. Churchill, 1921.) 21*s.* net.

THE entry of Dr. Brodetsky into the ranks of workers on aeronautical topics marks an important development in the higher study of aerial navigation. Why the achievements of modern aviation have not from the outset been built up on a substructure of purely abstract mathematical theory such as has arisen concomitantly with other branches of physics and engineering is difficult to understand. The behaviour of laminæ and other bodies moving through a medium under assumed laws of resistance, whether artificially propelled or otherwise, opens up a vast collection of problems which might well have occupied the attention of mathematicians and been illustrated by experiments with models long before the evolution of the full-sized aeroplane. Instead of this being done, flying machines have been built, flown, wrecked, and their pilots killed, by designers who have not even fully appreciated such elementary facts as that when an aeroplane is moving with uniform velocity the forces acting on it must be in equilibrium, that three forces in equilibrium must meet in a point, that an aeroplane has six degrees of freedom, that stability and equilibrium are not the same thing, and so forth. Whether the Tarrant triplane could have been saved by a full appreciation on the part of its pilots of the validity of the equation of *initial* angular acceleration, $Id^2\theta/dt^2 = M$, or numerous aviators saved from death by a better knowledge of the forces and couples on which longitudinal and lateral stability depend, are debatable questions. Meanwhile mathematicians of repute have attacked the writer of this review for intimating that a fuller theoretical study of the problem should be undertaken.

The National Physical Laboratory and the Royal Aircraft Establishment have absorbed many of the most enlightened of our university graduates who are competent to study aeronautical problems, and they are doing excellent work there. But, unfortunately, the amount of constructional work that had been going on while the mathematicians of our universities were making and marking examination questions, with their eyes shut to the outside world, has thrust on our Government institutions vast arrears of questions arising out of the engineering and physical difficulties associated with aviation. It is therefore not surprising that scarcely any one previous to Dr. Brodetsky has started at the opposite end and tried to fathom the capabilities of pure mathematical reasoning as distinct from experiment in throwing light on the study of aeronautical problems.

A notable exception is afforded by Mr. Lanchester, whose two volumes certainly represent a genuine attempt to investigate the behaviour of aeroplanes as deduced from *a priori* reasoning. But the subject was bristling with mathematical difficulties of a cut-and-dried character quite outside the scope of Lanchester's resources, and no mathematician would take up the challenges so oft repeated in NATURE until Dr. Brodetsky came on the scene. Contrast this state of affairs with the past history of electrical engineering, in which subject mathematical tripos candidates were being worried with solutions of Laplace's equations for infinitely long charged cylinders and conditions for solenoidal and lamellar magnets long before Lord Kelvin presented Peterhouse with its electric light.

In recent years nearly every publisher has decided that there is a demand for an up-to-date book on aeronautics, and has got some one to write one. In all these books the effects of the policy of "putting the cart before the horse" is painfully evident. The mathematics is usually of a very elementary and insufficient character until we are confronted with the invariable chapter headed "Stability, Mathematical Theory." This is usually nothing more or less than a mutilated copy of part of the "Science Monograph" on "Stability in Aviation" by the present writer, accompanied by a misuse of signs and symbols and a total disregard for all the accepted doctrines

regarding elegance of mathematical style and form that are calculated to produce chaos and confusion in the study of stability for years to come.

In presenting students of aeronautics with the first treatise that is thoroughly imbued with the ideals and spirit of the best mathematical school of Cambridge, Dr. Brodetsky is performing for aviation what Clerk Maxwell accomplished in anticipation of modern electrical engineering. In both cases the authors have undoubtedly been striking out on new lines and breaking fresh ground with scanty information to guide them as to choice of subject-matter, method, and order of treatment. The subject has thus opened up an almost illimitable collection of unsolved problems of which Dr. Brodetsky's treatise breathes in nearly every line.

As in electrical text-books, Dr. Brodetsky starts with the simplest problems, but unlike them, appears to avoid their subsequent contradiction of previous results. After a short introduction involving a summary of the problems presented by the heavier-than-air machine, section 1, dealing with "Motion in Air," opens with a chapter on "Dimensions," dealing with elementary dynamical principles, in which account is taken of such possible influences as viscosity. At this early stage important innovations in the matter of notation become necessary. If the object of the writers who are continually changing their axes is to avoid copying the original stability monograph, they would have caused less confusion if they had adopted different letters. Now that L_p may mean M_q or $-N_r$, it has become necessary to scrap the original notation and substitute an entirely different set of symbols. It is to be hoped that the same mistake will not again be made, but that Dr. Brodetsky's notation for the so-called "derivatives" and similar quantities will be accepted as a permanent solution for the present chaos. It certainly represents the best that could be evolved after many hours of consideration, in which the present reviewer took part when studying with Dr. Brodetsky through a grant from the Research Department under the hospitable roof of Bristol University.

The next chapter deals with problems on resisted motion falling within the range of particle dynamics, including a study of Lanchester's phugoid curves. The reference to "catastrophic instability" on p. 53 is important in view of the frequent Press notices of aeroplanes which are stated to have turned over suddenly and crashed to the ground.

Two-dimensional rigid dynamics forms the subject of the next chapter, which embraces not only the ordinary theory of longitudinal stability (including a *rigorous* proof of Routh's discriminant condition), but also applications to the kite and parachute. Further, there is an original investigation of the motion under gravity of a lamina under an assumed simplified law of resistance which is illustrated by diagrams deduced from theory and compared with experiment. The reference to periodic solutions should receive serious consideration. It must not be forgotten that an aeroplane may be stable for small deviations from steady motion and may yet be capable under suitable initial conditions of acquiring a periodic motion turning over and over in loops until it crashes to the ground, while it may be impracticable to extricate it from this state. The aeroplane which effected a successful landing after its observer and pilot had been shot dead did not necessarily possess immunity from this danger, which might have occurred if the machine had started under different initial conditions.

The next chapter deals with applications of three-dimensional rigid dynamics. Here the range of solved problems is necessarily limited. It, however, includes circular and spiral flights and lateral stability of the aeroplane, the parachute and the kite. In these sections Dr. Brodetsky's notation is a great improvement on its predecessors. It has the great advantage that, like the notation in the original treatment of stability, it makes the terms of the biquadratic all positive. In the same way it is much easier to write down the pressure equation in hydrodynamics with the old-fashioned velocity potential instead of the new one.

As regards section 2 ("Dynamics of Air") there is less to be said. The one direction in which mathematicians have made a serious attempt to do substantial work more or less connected with aeronautics (often less) has been in applying hydrodynamics — mainly two-dimensional hydrodynamics of perfect incompressible fluids—to the study of pressures on moving laminæ. In this connection Dr. Brodetsky gives a good general treatment of discontinuous motion. The book as a whole, however, is calculated to emphasise the importance of rigid dynamics as applied to aircraft in their entirety in contrast to these popular hydrodynamical investigations of flow of air round parts of their structure, which, as a matter of fact, are largely affected by mutual interference. It is to wind channel experiments that we must look for the determination of the quantities required in theoretical developments.

In section 3 Dr. Brodetsky returns to the original methods of treatment, and we are glad to notice his recognition of the concept of the ideal "narrow planes gliding at small angles" as having made it possible to initiate a formal study of stability in anticipation of the modern wind tumult. In the

next sections he gives a theory of the propeller, while chap. 8 deals with the problem of the aeroplane in moving air. Following Prof. E. B. Wilson the treatment is based on the study of forced oscillations, but the reader will do well to follow Dr. Brodetsky's advice and read his alternative treatment by the method of initial motions. This latter method, by the way, opens up an almost unlimited supply of calculable problems which cannot fail to throw light on questions regarding design and control of aircraft which are under the direction of their pilots.[1]

A further important innovation is the insertion of collections of exercises, commonly described as "Examples." Here again Dr. Brodetsky has had the difficult task of striking out in a new line in incorporating the features of a Cambridge text-book in an aeronautical treatise. This feature will, we hope, be of great use in making the present important developments of applied mathematics available in our honours schools.

A further contribution to the study of aeroplane mathematics by Dr. Brodetsky appeared in the *Mathematical Gazette* for May 1921. It dealt mainly with the conditions of equilibrium of the forces acting on an aeroplane in steady motion of different types, such as horizontal flight, climbing, descending, gliding with or without varying the elevator, diving and upside-down flight, load variations, variation of air density with altitude, flight in steady wind, and circling and helical flights with and without sideslip. In conclusion Dr. Brodetsky remarked: "The present paper will perhaps suffice as an indication to teachers of mathematics and others of how much really useful and interesting information can be obtained with easy mathematics. The introduction of aeroplane mathematics into ordinary courses in all our schools and universities would be a great boon to teachers as well as to pupils."

In addition to strongly supporting Dr. Brodetsky's plea for the study of aeroplane problems by mathematicians and their pupils, we would refer to the equally important task which remains, of equipping the workers in the aeroplane industry with a better knowledge of the principles of mechanics involved in aircraft construction and manipulation. In this connection it is to be hoped that the Institute of Aeronautical Engineers, now two years old, will prove a valuable addition to the roll of similar technical and professional institutes that have been formed in nearly every other branch of applied science, the ranks of which are largely recruited from the students of our technical colleges and universities. For such students Dr. Brodetsky's book is specially suitable.

G. H. BRYAN.

[1] The investigations which the writer of this review was able to initiate and undertake with the assistance of a three-years grant from the Research Department could not for various reasons be incorporated in Dr. Brodetsky's treatise, but have been published in the Reports and Memoranda of the Advisory Committee for Aeronautics and the Aeronautical Research Committee, Nos. 555, 640, 684, 689, and 744, the last two dealing with the general equations of motion of aeroplanes studied from several novel points of view with the use of Brodetsky's notation. The last Report constitutes a brief exposition of the general theory of initial motions in its application to aeroplanes.

The History of Whaling.

A History of the Whale Fisheries: From the Basque Fisheries of the Tenth Century to the Hunting of the Finner Whale at the Present Date. By Dr. J. T. Jenkins. Pp. 336. (London: H. F. and G. Witherby, 1921.) 18*s*.

AT the close of the last century whaling appeared likely to terminate at an early date, in view of the great reduction in the numbers of whales which had been brought about by a relentless and long-continued persecution. The rate of destruction had been accelerated by the introduction of modern methods, and if new fields had not been discovered whaling might by now be almost a thing of the past. Dr. Jenkins's book contains a large amount of information which will be of great value to those who wish to satisfy themselves whether the lessons of history confirm the forebodings which have been expressed about the future of whales.

The work opens with an account of whales, their species, habits and migrations, and zoologists may turn with interest to an Icelandic classification (p. 87) of 1777, which within its limits is not inferior to the most modern system, or to the excellent account of the Greenland whale (p. 116) given by Edge, who took part in Arctic whaling in 1610. The next chapter deals with the products of whales, the method of hunting, and whaling legislation, giving also a brief review of the successive phases of the industry, a subject which is considered in greater detail in later chapters. Whale-oil, a material which was formerly indispensable for the lighting of houses, public buildings, and streets, has remained one of the most important raw materials for the manufacture of soap and glycerine, the great quantities of glycerine which were extracted from it during the war having been of vital importance to this country. Spermaceti, ambergris, and whalebone are still highly valued materials, while the greater part of the carcasses of whales is utilised in the preparation of agricultural manure, the flesh being partly converted into cattle-foods or even used for human consumption.

The first known account of whaling is that of Ochther, who voyaged beyond the North Cape towards the end of the ninth century, and afterwards described

his journey to King Alfred (p. 59). The whale industry of the Bay of Biscay, depending principally on the Atlantic right whale, can also be traced back to an early date, since it was at its apogee in the twelfth and thirteenth centuries (p. 61). The Basques appear to have voyaged to Newfoundland as early as 1372 (p. 64), thus anticipating Columbus by more than a century. It will perhaps surprise the general reader to learn that train oil, a name derived from the Dutch *traan*, a tear or drop, is mentioned as a material "to the great commodity and benefit of this our Realm of England," in a grant by Queen Elizabeth, 1576–7 (p. 303).

For nearly three centuries the Greenland whale occupied a position of special importance in the industry, at first in the neighbourhood of Spitsbergen (from about 1604), later in Davis Straits (from 1718), and in the North Pacific and the Arctic Ocean beyond Bering Straits still later (from 1846). The sperm whale industry had meanwhile become so important as to rival that based on the Greenland whale, starting off New England about 1614 (p. 223), and afterwards extending into the Atlantic, Pacific, and Indian Oceans. The Pacific grey whale was hunted for a relatively short period off the coast of California, an original method of capture having previously been invented by the Indians. The operations off Iceland, Newfoundland, Japan, the British coasts (on a larger scale than is generally recognised), and Spain are described in the concluding chapter, which also deals with the specially important modern development of whaling, carried on since 1905 in the neighbourhood of the Antarctic continent, as well as off the coasts of South Africa and South America. This subject, of urgent public interest, deserved fuller treatment.

Dr. Jenkins does not sufficiently emphasise in his work the deplorable reduction in the number of humpbacks within five or six years from the commencement of operations off South Georgia, and he seems to regard this species as still very common off the South African coasts (pp. 295, 296). In suggesting a winter Antarctic close season (p. 299) he is not up to date, as this measure has recently been authorised by the Colonial Office, while the list of the chief existing southern whaling areas on p. 292 gives no hint of the predominance of South Georgia and the South Shetlands, nor does it indicate that whaling operations in the South Orkneys, Australia, Kerguelen, and other localities are extinct or of negligible importance. It would scarcely be inferred from the account of the African stations how great has been the shrinkage of the industry within the last decade. The impoverishment of the natural resources of the world due to the operations of the whalers, and obvious from their own records, might have been explained with greater emphasis. The statement (p. 234) that the discovery of petroleum in 1859 sealed the fate of American whaling can scarcely be described as the only cause, for the diminution in the number of whales which was taking place must have had some influence in producing this result.

It is melancholy to compare the existing distribution of whales with their former abundance. The Greenland whale occurred in profusion in the bays of Spitsbergen at the commencement of Arctic whaling, and the Varanger Fjord during March "simply bubbles or boils" with humpbacks (p. 32). Atlantic right whales regularly passed Biarritz towards the end of the seventeenth century (p. 64), while whales were plentiful off New England in 1614, where an early writer speaks of "mighty whales spewing up water in the air like the smoke of a chimney, of such incredible bigness that I will never wonder that the body of Jonah could be in the belly of a whale" (p. 223). These occurrences are now mostly things of the past and though Dr. Jenkins fully recognises the fact, he is perhaps not sufficiently convinced of the danger of extinction.

The production of whale-oil is usually estimated in barrels, and some discussion of the capacity of this measure would have been useful. The book must be read carefully to discover a reference (p. 244) to barrels of thirty gallons each and a statement (p. 293) that the standard size is now six barrels of oil to one ton. On p. 294 the question is unnecessarily complicated by giving the oil production for Natal in pounds for 1909, in barrels and tons for 1910, and in pounds for British South Africa, 1910. Scoresby (1820) had already stated that the ton consisted of 252 gallons, and had given experimental estimations of the number of pounds of oil to the gallon at different temperatures; from his remarks, however, on the gauging of casks and from his list of stores, where he says that the casks should be of sizes suitable for stowage, it is obvious that the barrel was not a definite measure. There is probably considerable uncertainty as to the extent of a catch estimated as so many barrels of oil.

The figures given by Dr. Jenkins occasionally arouse doubts as to their accuracy, as on p. 268, from which it would appear that, after deducting the value of the baleen, a blue whale is worth 90*l.* and the smaller fin whale 110*l.* In other cases sufficient care has not been taken to explain that a statement is no longer correct, as in the account (p. 29) of the Pacific grey whale, which has ceased to be common on the coast of California. Exception may also be taken to p. 265, representing the facilitation of the capture of the *smaller* whales as the principal result of the introduction of Svend Foyn's harpoon-gun. The statement (p. 293) that whalebone is worth from 39*l.* to 45*l.* a ton is

ambiguous, since the list to which it refers includes not only the Rorquals, but also the Greenland whale. It appears from another page that the whalebone of the Greenland whale fetched 1250*l.* a ton in 1901, and even this falls far short of the highest price it is known to have reached.

Some points might have been brought out more clearly by relegating details to tables in which one year could easily have been compared with another. By setting these facts out at length in his main narrative the author has failed, to some extent, to give a correct perspective of the general trend of events. There can be no doubt that whales have diminished in number, and Dr. Jenkins's book will do real service if, by calling attention to the history of the past, it awakens interest in the urgent necessity of so regulating the industry as to avoid the disaster of completing the destruction of animals which must rank as among the most wonderful of mammals. The book contains much information extracted from State papers and other old records at home and abroad, special attention having been given to the Dutch whaling literature. Many of these documents are so inaccessible that the gratitude of zoologists is due to Dr. Jenkins for this service.

Inorganic Chemistry as a Science.

Handbuch der anorganischen Chemie in vier Bänden Edited by Prof. R. Abegg and Dr. Fr. Auerbach. Vierter Band. *Erste Abteilung, zweite Hälfte. Die Elemente der sechsten Gruppe des periodischen Systems. Zweite Hälfte.* Edited by Dr. Fr. Auerbach. Pp. xiii+1072. (Leipzig: S. Hirzel, 1921.) 140 marks.

ALL chemists will rejoice at the appearance of another volume of the well-known Abegg-Auerbach "Handbook of Inorganic Chemistry," and we desire to offer Dr. Fr. Auerbach our hearty congratulations on his success in carrying on so worthily the great work begun by Abegg. The last volume, dealing with F, Cl, Br, I, and Mn, appeared in 1913. As the editor states in the preface, the appearance of the present volume has been delayed by the European war. It deals with the elements Cr, Mo, W, and U, which belong to the sixth group of the periodic table. It is intended that O, S, Se, and Te shall be dealt with in a later volume.

The authorship of the monographs contained in the present volume is as follows: Chromium, Molybdenum, and Tungsten, J. Koppel; Uranium, R. J. Meyer; Hetero-poly-acids, A. Rosenheim.

The famous writer of the articles on atomic weights in the previous volumes—Brauner—has now dropped out and his place is taken by J. Meyer. Similarly we miss the name of Lottermoser in connection with the articles dealing with colloid chemistry, these being now written by G. Jander.

A very important part of the volume under review is the extensive monograph by Rosenheim on the hetero-poly-acids and their salts. Although the corresponding complex anions may be derived from elements other than those dealt with in this volume, these compounds have been treated as a single group and included in the present volume, since molybdenum and tungsten are amongst the constituents which occur most frequently in these anionic complexes. This is a happy idea and a most useful one, for the monograph by Rosenheim is probably the first really comprehensive and satisfactory survey of this difficult subject that has appeared.

Of the 1064 pages (omitting the subject index) in the present volume, 465 are occupied by the article on chromium. This is undoubtedly one of the finest chemical monographs ever written and must have cost the author an immense amount of thought, labour, and time. We all owe him a great debt of thanks for his splendid work. Attention may be directed specially to his exhaustive treatment of the complex chromi-ammines (which alone occupies eighty-two pages), the anionic chromi-complexes, the passivity and "electromotive" behaviour of chromium, and the heterogeneous equilibria in which chromium compounds are involved.

Under tungsten there is an excellent account of the tungsten filament lamp and the methods of preparing and treating metallic tungsten, while the monograph on uranium and its compounds by R. J. Meyer contains a very good account of the physical chemistry of the uranyl compounds.

But where everything is so good, it is difficult to select any special part for particular mention. Thus the articles on atomic weights and on colloid chemistry by J. Meyer and G. Jander respectively appear to be quite up to the high standard set in previous volumes. We can give the present volume no higher praise than to say that it would have rejoiced the heart of Abegg. Of the great "Handbook" it can still be said that it must be in the possession of, or readily accessible to, every scientific chemist, whatever may be his special occupation or province of work. It constitutes a re-writing of inorganic chemistry on the basis of the pioneer work of Mendeléeff, Gibbs, Rooseboom, Thomsen, Arrhenius, van't Hoff, Ostwald, Nernst, Abegg, Bodländer and Werner. It does for the present generation what the great work of Gmelin did for a previous one. It utilises thermodynamics and the theory of ions in carrying inorganic chemistry another

stage forward on its journey towards the ever-unattainable goal of perfect knowledge. It is still the history of the individual written from the behaviour of the crowd. Some day another Abegg will tell the story of the next stage, perhaps the history of the crowd written from the behaviour of the individual. However that may be, we chemists of the present generation cannot be too grateful to Abegg for the work which he did in bringing inorganic chemistry abreast of the progress of chemical science.

F. G. DONNAN.

Cloud-Forms.

Le Nubi. By L. Taffara. Parte 1, Testo. Pp. 67. Parte 2, Atlante. Tav. 26. (R. Ufficio Centrale di Meteorologia e Geodinamica Roma.) (Roma: Tipografia Ditta L. Cecchini, 1917.)

THE recent revival of interest in cloud-forms which has expressed itself in the publication of various collections of photographs is well illustrated by the atlas which was prepared by Signor L. Taffara and issued in 1917 by the Meteorological Institute of Rome, together with an introductory text which is reprinted from vol. 37 of the Annali of the institute.

The text leads up to a chapter on procedure in the observation of the height and motion of clouds. On the way it explains the history of the study of clouds on the basis of international agreement, the original specification of ten cloud types, the international atlas of 1895, the revision at the International Conference at Innsbruck in 1905 and the republication of the atlas in 1910, which included the ten types and nine variants with a special note on clouds of a type called "lenticularis," the importance of which becomes increasingly evident. In the meantime (1907) the late M. Vincent, of the observatory at Uccle, Brussels, had published an atlas of cloud-forms with much more elaborate classification, which had been followed by Dr. Loisel, of the observatory of Juvisy (Paris), in 1911. The suggested classification includes nine species, comprising twenty-one varieties of lower cloud; two species, twelve varieties of middle cloud (which may further require one of the adjectives "undulatus," "striatus," or "mammatus"); and four species, nineteen varieties of high cloud, which may require further discrimination as "undulatus," altogether fifty-two forms of cloud to be discriminated, or upwards of one hundred if discrimination by adjectives is included. Of the many additional variants that are thus introduced, two—namely, pallio-nimbus, which seems to be a good formula for a rainy day, and alto-cumulus castellatus, a sign of approaching thunder—seem to have acquired merit. Signor Taffara accepts this classification as being the most complete, and in his atlas gives forty-nine photographs (including three autochromes), most of them by himself, but some by Mascari, Loisel, Gamba, Ponte, Peret, Neuhaus, a pastel by Scalla, and two water-colour drawings, which illustrate thirty-six of the hundred examples, and one more type in addition, which is defined as "lenticularis." It does not occur in the list quoted from Vincent. The reproduction of the photographs is excellent; the art of photography of clouds is the subject of a special chapter of the text. The collection forms a beautiful book.

Among the pictures are two very definite types of cloud which belong to the region of Mount Etna and are admirably represented by reproductions of Signor A. Marcari's photographs; these are "la serpe," a long serpentine cloud shown straggling along like a snake, low on the mountain; and "Contessa del vento," a stationary cloud of the Valle del Bove, of which no fewer than five examples are given. These clouds are disposed of in the classification as being "cumulus humilis," in association with other cumulus of low level; but the obviously lenticular nature of the "Contessa del vento" marks it out as being something entirely different from any of the hundred forms. It looks like a gigantic white turban, the crown of which merges into other clouds, and it suggests the core of an eddy, possibly formed mechanically by the mountain, since all lenticular clouds seem to be associated with peculiar dynamical conditions due to the unevenness of the surface. If the lenticular shape indicates the locus of formation of cloud in wind that blows through the cloud, not with it, as it appears to do in other cases, we have apparently in these clouds an opportunity for studying the conditions at close quarters.

We are scarcely yet in a position to make a final classification of clouds, and the elaborate classification into some hundred forms is somewhat premature. Presumably we should begin by drawing a distinction between individual clouds and cloud-groups. Cumulus is a cloud, alto-cumulus a cloud-group. It is questionable whether a vast layer which discloses small cumulus on its margins is fairly classified by the appearance of the cloudlets there. We have no sufficient principles of classification, and for that reason a multitude of discriminatory characteristics scarcely helps us at this stage. The contribution to our knowledge of different forms which the Ufficio Reale has made through the agency of Prof. Taffara is a valuable addition to the material from which classification will at some time emerge. It seems

desirable that the path should not be encumbered beforehand with too many adjectives, though it may be confessed that Latin adjectives have a peculiar fascination. They trip so lightly off the tongue that when one begins to use them one scarcely knows where to stop.

Napier Shaw.

Prehistoric Western Europe.

(1) *The New Stone Age in Northern Europe.* By Prof. J. M. Tyler. Pp. xviii+310. (London: G. Bell and Sons, Ltd., 1921.) 15*s*. net.

(2) *Man and His Past.* By O. G. S. Crawford. Pp. xv+227. (London: Oxford University Press, 1921.) 10*s*. 6*d*. net.

We gladly extend a welcome to these two books as real signs of a publishing revival as well as of the widespread interest in the far past due to the diffusion of the idea that, when some day we find the right clues, prehistoric Western Europe will become almost as fascinating as the prehistoric Ægean has become through the great advances of knowledge in the last generation. Both writers have in view the general public, but their aims are very different. Prof. Tyler has striven to interpret the results of research up to about 1912 so as to give the reader a fairly connected story, but in spite of cautious reserve, here and there he unfortunately obscures many difficulties, and suggests that knowledge exists where the careful worker knows only the depths of ignorance. Mr. Crawford, like Prof. Tyler, has also an annoying habit of discursive remarks on things in general, and these irrelevancies make his book larger than it need have been; but his valuable purpose is evidently to stimulate the local archæologist and to enlighten him as to methods in those provinces of study which he can legitimately occupy.

It is a sign of progress that both books look back to Déchelette, the acceptance of whose work now marks any book that claims serious attention, at any rate if it deals with Palæolithic times. But Prof. Tyler carries over a great deal from far older and less trustworthy sources into the new period and gives us a most dangerous sketch of the coming of the "Indo-Aryans," that name of ill omen in archæology. Moreover, he has not taken Déchelette's maps to heart, and needs to learn the lesson Mr. Crawford sets out to teach, namely, that finds and prehistoric remains of all kinds need to be mapped accurately for serious geographical study. Mr. Crawford will not think it amiss if we say that among his papers (*e.g. Geog. Journ.*, 1912) are many things that teach the lesson more effectively than this present book. None the less, precept does come with a certain appropriateness from a well-known practician, and Mr. Crawford's suggestions about road tracing imply that he is going to develop the archæological data on our ordnance maps in his new and appropriate position as Archæologist to the Ordnance Survey.

(1) After reading Prof. Tyler's book, one is more than ever convinced of the need for a careful resurvey of all the evidence for the periods that are commonly supposed to intervene between the Magdalenian and the beginning of the Bronze age. Some megaliths almost certainly belong to the Bronze age even if bronze finds do not occur in them, and some of the finds of polished stone axes, and so on, are in danger of being shown to belong to the Metal ages. On the other hand, some finds of flints of Azilian and perhaps earlier types are likely to be shown also to belong to later dates and even to the Iron age. In other words, survivals of late Palæolithic cultures seem to have lingered on into the Metal ages in N.W. Europe, and metal seems to have come in gradually, locally, and partially, so that the so-called Neolithic period, while still acknowledged to be real enough, is seeing both its limits fade away. Prof. Tyler is perhaps justified in neglecting these refinements, but a more definite consciousness of them, as well as a study of the files of the Journal of the Royal Anthropological Institute, especially for Mr. H. J. Peake's papers, would have helped him over many a stile.

Perhaps his chapter on Megaliths is the most inadequate in a book that must be considered, broadly, a failure, in spite of several points which are at any rate suggestive. Take, for example, the contrasts in distribution between so-called dolmens and *allées couvertes*, and the similarities between the spread of the latter and that of menhirs. The peculiar localisation of holed dolmens, the relation of the *allée couverte* to the English long barrow and the Scottish long cairn, whether holed or not, as well as to the *Ganggräber* of North Germany, are all points for serious study by the next person who tries to make a prehistoric synthesis. The views of Perry and others about the relation of dolmen building to metal seeking—prospecting for gold, copper, and tin—should have been studied critically; while Abercromby's "Bronze Age Pottery," with its discussion of the beaker, should have been brought into relation with the loess zone. With such study, a much more vital view of line of movement round about the end of the Neolithic age would have been gained. We greatly need a synthetic statement of the diverse movements of that transition time heralding the opening of the Bronze age with its concentration of attention on the gold of Ireland and so on the ways of getting to it. The succession of shell mound and dolmen (*allée*

couverte) on the same site, as in Guernsey, is another fruitful line of thought, and no synthesis should neglect M. de Guérin's amplifications of Déchelette's views on ancient incised figures and idols.

The movements outlined above must be taken into account by linguists who wish to find a link with archæology, and it will probably be through the forging of that link that the great advance we look for will occur. It is possible to argue for the spread of at least some elements of the languages of the older philologists along the lines of distribution of beaker pottery, but it is quite likely that those language elements travelled far later, with other archæological correlatives, along the line determined in large measure by the presence of loess and the consequent weakness of forest and swamp. One may venture the statement that probably rather by such study than by the more exclusively philological ones suggested by Prof. Tyler will our knowledge of the sources of the European languages be improved, and our views as to their adoption, with modification, by peoples who were not bred with them, made precise. Anyhow, it seems more than likely that our great families of European languages in several cases illustrate adoption of a language-basis from foreigners rather than differentiation of languages by process of time from a single common ancestor. The references to early religion that Prof. Tyler gives seem specially dangerous in the dim light of present-day doubt.

(2) Mr. Crawford's book shows he has been trying to set his thoughts in order after the trials and difficulties of war service, and, in the midst of discursive generalities, one does frequently come upon points of value for the student who wants to take his archæology regionally and to see man at each period in his proper relation to the local environment of that period. Fortunately, Mr. Crawford is alive to the fact that the environment changes with the period even after the close of the Ice age. He sees that the clearing of forests and the draining of swamps have made vast differences to men's opportunities for movement and lines of communication, and he understands the difficulties of argument on these complex problems. He is an impassioned eulogist of old roads and of the joys of tracing them, and the beginner in prehistory who is anxious to get hold of method, rather than of fact, will find Mr. Crawford's book interesting and profitable, though he may be left wondering why the author did not omit a good deal of general talk and give the student a great deal more help along his way.

H. J. F.

Rosenbusch's Petrology.

Mikroskopische Physiographie der petrographisch-wichtigen Mineralien. By H. Rosenbusch. Band 1. Erste Hälfte. *Untersuchungsmethoden.* Fünfte, völlig umgestaltete, Auflage. By Prof. E. A. Wülfing. Lieferung 1. Pp. xvi+252. (Stuttgart: E. Schweizerbart'sche Verlagsbuchhandlung (Erwin Nägele), 1921.) 16*s*.

ALL who are interested in petrological studies will welcome a new edition of this familiar text-book, which made its first appearance nearly forty years ago. Every subsequent edition has exceeded its predecessor in size and completeness, and the fifth, to judge from this instalment of the first half of the first volume, is not likely to prove an exception. It is true that some of the topics dealt with in earlier editions, such as the principles of stereographic projection, are omitted as being now sufficiently familiar to the student, but the space thus saved, and more, is required for the developments during the seventeen years that have elapsed since the previous edition was published.

This issue is the work of Prof. E. A. Wülfing, the author of the admirable account of the methods employed in the microscopical examination of minerals in the fourth edition of the book, and the successor of Rosenbusch at Heidelberg. It has been to a large extent rewritten, and there is a decided advance in the clearness with which the fundamental principles are explained, even if the mathematical aspect of the subject is perhaps still somewhat over-emphasised in places.

The first forty pages are mainly devoted to a detailed description of the most up-to-date methods of cutting, grinding, and mounting thin slices of rocks. This is followed by an exposition of the author's views on the nature of light and an account of its properties in both isotropic and anisotropic media, including the phenomena of absorption and pleochroism. There is also a useful section devoted to the methods of producing polarised light in which the different forms of prism that have been devised for the purpose are described, and another to the production of monochromatic light.

The text is accompanied by numerous clearly drawn illustrations, many of which appear for the first time, and there is a handsome coloured plate giving the succession of Newton's colours, the amount of relative retardation corresponding to the different tints, and the usual graphic representation of the relation between birefringence, thickness, and relative retardation.

JOHN W. EVANS.

Our Bookshelf.

An Agricultural Atlas of Wales. Made on behalf of the Institute for Research in Agricultural Economics, University of Oxford, by J. Pryse Howell. Pp. iii + 23 maps + 3 maps in pocket. (Southampton: Ordnance Survey, 1921.) 5s. net.

IT is to be hoped that the enterprise of the Ordnance Survey in publishing an agricultural atlas of Wales will be rewarded sufficiently to facilitate the publication of similar atlases for regions of England. Mr. J. Pryse Howell has worked at agricultural surveys for years at Aberystwyth and at Oxford, and the present atlas does considerable credit to his care and industry. It is based on parochial returns, and consists of twenty-three maps, one for each agricultural product. There are also three loose maps in colour giving the orography, geology, and rainfall of Wales, and as the agricultural maps are on translucent paper they can be superimposed on the loose maps in order to trace correlations.

It is a pity that the revision of Welsh geology is not yet sufficiently complete to give a better representation of the stratigraphy of West Wales based on the work of Prof. O. T. Jones and the correlation with geological facts. The correlations traceable often depend more on the drift than on the solid geology, though these maps of Wales are mostly of a kind simpler than one would find in England, for in Wales the greater part of the surface is impervious soil on hard rocks, and agriculture is dominated by orographical conditions which so greatly influence rainfall. In England the influence of soil would be more complex.

The agricultural relations of the belt between the Vale of Clwyd and the Dee at Corwen, of the lower Montgomeryshire Severn, the parallels between pigs and potatoes, and many other points, stand out clearly, while the curious distribution of lucerne, sainfoin, clover, and grasses under rotation prompts a number of questions. The atlas should be used widely by agriculturists and economists, by persons interested in local administration, and by teachers, especially teachers of geography.

The Silver Bromide Grain of Photographic Emulsions. By A. P. H. Trivelli and S. E. Sheppard. (Monographs on the Theory of Photography from the Research Laboratory of the Eastman Kodak Co.) Pp. 143. (New York: D. Van Nostrand Co.; London: Kodak, Ltd., 1921.) 15s.

THE research laboratory of the Eastman Kodak Co. has in preparation a series of monographs on the theory of photography. The time is ripe for the presentation in a connected sequence of the work done and the results obtained, for these are very numerous and very scattered. The present volume is the first issued, and presumably may be regarded as a sample of those that are to follow. The company, the laboratory, and the authors are to be congratulated in that they have made so good a beginning. The authors have been engaged for some years in the practical study of the subject with which they deal, and they give some results that have not been published before. A study of the relations that exist between the sizes of the grains and their photographic properties is reserved for a future monograph, though it is by no means neglected in the present treatise. The first half of the volume deals with the influence of ammonia on photographic emulsions and a theory of ripening; von Weimarn's theory and the determination of the dispersity of silver bromide precipitates; accessory factors influencing the dispersity of silver bromide emulsions; crystallisation catalysis; and capillarity and crystalline growth. The intimate relation between grain structure and photographic properties is, however, fundamentally a matter of crystallographic investigation, and the remainder of the volume is devoted to this matter in five chapters. The authors state that "when the experimental conditions regulating the three primary factors, (1) dispersity-distribution, (2) recrystallisation, and (3) sorption (both adsorption and desorption), are completely known, scientific control of the characteristic curve—*i.e.* of speed, latitude, and density—will be possible." The book is copiously illustrated and well indexed; it has many summaries, all necessary references, and an extensive bibliography. C. J.

Indian Science Congress: Handbook for the Use of Members attending the Ninth Meeting to be held at Madras from the Thirtieth of January to the Fourth of February, 1922. Pp. x + 165. (Madras: Capt. Clive Newcomb, Chemical Examiner, 1921.)

THE Indian Science Congress has held annual meetings in various parts of India yearly since 1914 much on the lines of the British Association for the Advancement of Science, and the handbook issued for this year's meetings contains a number of interesting articles by experts, including a brief history of Madras and its Corporation, descriptions of the museum and Connemara Public Library, the Madras Harbour, the new city waterworks and the chlorination purification of the supply, and an interesting account of places of historical interest within twenty miles of the city. General education in Madras is dealt with by the principal of the Presidency College, and medical education by the principal of the Medical College. The remainder of the little book is occupied with accounts of scientific work in the Presidency in different branches of knowledge, and includes the work of the King Institute of Preventive Medicine, situated several miles from the city and concerned chiefly with hygiene, and an interesting account of the valuable practical investigations being carried out at the Agricultural and Research Institute at Coimbatore by the Director of Agriculture. Contributions on prehistoric archæology, the anthropology of Southern India, marine zoology, the geology of Madras, and biological work there, complete an instructive handbook which is very suitable for the purpose for which it has been designed. L. R.

Treatise on Fractures in General, Industrial, and Military Practice. By Prof. J. B. Roberts and Dr. J. A. Kelly. Second edition, revised and entirely reset. Pp. x + 755. (Philadelphia and London: J. B. Lippincott Co., 1921.) 42s. net.

THE authors of this volume have set out, as they claim in their preface, to present a lucid view of the subject

in the light of recent discoveries, to point out an accurate scientific procedure, whether operative or other, according to the character of individual injuries, and to urge the general practitioner, as well as the surgical specialist, to the study of methods which, as experience indicates, have given the best results.

As a consequence of experience gained during the war, the treatment of gunshot and other wounds of bones has been revolutionised, because the distinction between aseptic fractures with unbroken skin and those breakages of bone which have been exposed to infection has been fully grasped. The authors insist that much of the old teaching as regards the treatment of fractures still holds good, as, for example, Lucas-Championnière's dogma as to early mobilisation and gentle massage being valuable for restoring contour and function in fractures of shafts and joint-ends of bones. They urge the critical, intelligent, and frequent examination of fractures instead of a too absolute reliance on radiographic interpretations by inexperienced laboratory workers. The illustrations so very necessary in a descriptive book of this nature are, without exception, excellent, and will be found a great help in following the text. Indeed, it is the most complete and comprehensive book on a very important branch of surgery that we have yet seen and it may be regarded as one of the few good results of the world-war.

The Raw Materials of Perfumery: Their Nature, Occurrence and Employment. By E. J. Parry. (Pitman's Common Commodities and Industries.) Pp. ix + 112. (London: Sir Isaac Pitman and Sons, Ltd., n.d.) 3*s*. net.

DURING the last half-century perfumery has in part become a branch of synthetic organic chemistry. Many of the odoriferous constituents of natural perfumes (*e.g.* vanillin and heliotropine) are prepared synthetically in a pure state, and some substitutes (*e.g.* "artificial musk," trinitrobutyl xylene) for natural perfumes are now in use. The rare natural perfumes such as musk have not yet been produced in the test-tube. With the production of the materials, however, the perfumer's art has made only a beginning and much depends on the skilful blending of the constituents. Mr. Parry has given a simple and interesting account of his subject. It is non-technical, and perhaps might have included a little more of the chemistry involved. The latter is of so complicated a character that it would perhaps not have been intelligible to the ordinary reader. The address of the president of the Chemical Section of the British Association last year (NATURE, October 20, 1921, p. 243) shows, however, that something can be done in this direction.

Handbuch der biologischen Arbeitsmethoden. Edited by Prof. Dr. Emil Abderhalden. Leiferung 45, Abt. 5, *Methoden zum Studium der Funktionen der einzelnen Organe der tierischen Organismus.* Teil 7, Heft 2, *Sinnesorgane.* Pp. 197-260. (Berlin und Wien: Urban und Schwarzenberg, 1921.) 28.80 marks.

THE section on the analysis of sounds in Prof. Abderhalden's extensive "Handbuch" is written by Dr. E. Budde. It contains accounts of the use of mechanical integrators for the analysis of a periodic curve, and of the method of calculating the terms of the Fourier series from ordinates at regular distances apart. Tables are given to facilitate the calculation when seventy-two ordinates are measured per period. It is not often that so many ordinates are taken, but when it is necessary or desirable the tables will save much time and trouble.

A Course of Practical Organic Chemistry. By Dr. T. Slater Price and Dr. D. F. Twiss. Third edition. Pp. xiv + 239. (London: Longmans, Green and Co., 1922.) 6*s*. 6*d*.

IN this edition minor alterations have been made to bring the subject-matter up to date. The methods of preparation of typical organic compounds and the quantitative analysis of compounds of carbon, hydrogen, nitrogen, the halogens, sulphur, and phosphorus, are well described. The scheme given for the identification of "an organic compound" is too incomplete to satisfy ordinary requirements, and could usefully be extended in future editions. Mixtures should also be considered.

Letters to the Editor.

The Langley Machine and the Hammondsport Trials.

THE leading articles in NATURE of November 3 and January 26 last appear to have missed the point of my discourse on the Langley Machine and the Hammondsport Trials. My paper was written to expose a fallacy in which officials of the Smithsonian Institution had used their great opportunities for imposing upon the public a false belief that the Langley machine had been flown in 1914.

The leading articles in NATURE, instead of making any denial of the charge that vital changes were made in the Langley machine at Hammondsport before any flight was attempted, contend that my "paper tends to give an erroneous impression of the importance of the part played by the Wright Brothers" in the producing of the first man-carrying aeroplane. NATURE suggests that it was Langley who did the laborious work of preparing the scientific data upon which the first aeroplane design was based, and that the Wright Brothers merely contributed the system of wing warping—the final step or "keystone"—in the problem of flight. The writer of the articles in NATURE refers to Sir Richard Gregory's book "Discovery," from which he makes two quotations.

I agree with the author of "Discovery" that many great inventions are based upon pure science, and that often the person who receives the credit for an invention is the one who has added some mechanism which turns the scientific knowledge of another to practical use. In the facts in regard to the invention of the aeroplane, however, the author of "Discovery" and the writer of the leading articles in NATURE are in error. The real truth of the discovery of flight is that the Wright Brothers first established a scientific basis for aeroplane design; they then invented the mechanical means for putting this scientific knowledge to practical use. The spectacular nature of the latter has blinded the public to the importance of the former.

In 1914, when I was beginning the preparation of my paper on the "Life and Work of Wilbur Wright," which was read in 1916 as the fourth Wilbur Wright Memorial Lecture, I visited America to collect material for this lecture. During my stay, which extended over several months, I also studied the practical side of aviation and, at the age of forty-seven, made over a hundred flights on the "unstable" Wright machine. While in Dayton I was allowed to examine, with the privilege of copying, much of the personal correspondence and diaries, as well as the records of the early purely scientific work, of the Wright Brothers. I saw the original balances and twenty or thirty (out of the great number) of the original test surfaces with which the Wright Brothers in 1901 made thousands of measurements in a wind tunnel of the lift and drift and the travel of the centre of pressure on plane and curved surfaces. Copies of the tables obtained from these tests were also given to others who were interested in the problem of flight.

These laboratory measurements (*Century Magazine*, September 1908, pp. 646-647) covered a field many times greater than had been covered by the work of all other experimenters together. But the importance of the measurements lay in their accuracy. These tables did not agree with the measurements made by Langley or by any of the other experimenters. The Wright Brothers, finding that all marine propellers at that time were based upon empirical formulæ, made a study of propellers by analysing the various dynamic reactions. From these studies they evolved a theory. The propellers used on their first power machine were probably the first ever designed from theory and not from experiment. They made extended studies into the principles of equilibrium, and in this field made important scientific discoveries. Their mechanical means for carrying some of these principles into effect were patented, and the resulting litigation attracted so much attention as to cause the scientific work upon which the patents were based to go without notice. It was upon their own tables and other scientific work that the Wright Brothers built their first power machine.

These scientific experiments were made entirely at the expense of the Wright Brothers themselves, and with no thought or expectation of any other reward than the satisfaction of discovering things unknown before and the honour that naturally comes as a result. It was not until they attempted to build a power machine to carry this scientific knowledge into practical use, an expense too great for their small means, that they took out patents.

My address on the "Langley Machine and the Hammondsport Trials" was not a criticism of Langley nor of his scientific work. This was not a point at issue in my paper. But since the writer of the articles in NATURE now brings this into the discussion, I feel that some of his statements should not be allowed to pass uncorrected.

NATURE is in error in attributing the discovery to Langley of the inherent stability effect of the dihedral angle of the wings adopted by Langley in his models. This method of maintaining lateral stability in calm air was published by Sir George Cayley a hundred years ago, and was used by Penaud in his flying models in 1870 and 1871. It has never yet been solely relied on for lateral balance in actual human flight, having been always supplemented by aileron control.

The writer in NATURE says: "So far back as July 23, 1891, a paper on his (Langley's) experimental researches is to be found in NATURE, showing that the flight of a man-carrying aeroplane was possible, and enunciating the fundamental principles for obtaining a design." The demonstration referred to as "showing that the flight of a man-carrying aeroplane was possible," was stated on page 107, "Experiments in Aerodynamics," where Dr. Langley says, "such mechanical flight is possible with engines we now possess, since . . . one horse-power rightly applied, can sustain over 200 pounds in the air at a horizontal velocity of over 20 meters per second (about 45 miles an hour) and still more at still higher velocities." This statement was based upon the mistaken principle published by Sir George Cayley in Nicholson's *Philosophical Journal* of November, 1809, and accepted by most experimenters thereafter, that the pressures on a plane were normal to the surface of the plane, and that the drag was equal to the lift multiplied by the tangent of the angle of incidence. Langley's actual measurements did not confirm this theory, but he assumed (page 65, "Experiments in Aerodynamics") that if he had made certain modifications in the planes he was measuring other results would have been secured which would have confirmed it. It was this assumption that formed the basis of his demonstration that one horse-power would sustain 200 pounds at a speed of 45 miles an hour. As a matter of fact his actual measurements (page 64) showed that one horse-power could carry only 60 pounds at 45 miles an hour.

The other fundamental principle enunciated by Langley in 1891 was that known as the "Langley Law," which was that the faster an aeroplane be flown the less will be the power required to sustain it. The fallacy of this law is well known to all aeronautical engineers to-day, but up to 1910 this was generally considered as Langley's chief contribution to the science of aerodynamics. In that year when the Regents of the Smithsonian Institution decided upon the placing of a bronze tablet in the Institution commemorating Langley's work in aerodynamics, they ordered the following legend to be inscribed upon it:—

SAMUEL PIERPONT LANGLEY
1834–1906
SECRETARY OF THE SMITHSONIAN INSTITUTION
1888–1906.

AERONAUTICS:

LANGLEY LAW: "These new experiments show that if in such aerial motion there be given a plane of fixed size and weight, inclined at such an angle, and moved forward at such speed that it shall be sustained in horizontal flight, then the more rapid the motion is, the *less* will be the power required to support and advance it."—Langley, "Experiments in Aerodynamics," 1891, p. 3.

"I have brought to a close the portion of the work which seemed to be specially mine—the demonstration of the practicability of mechanical flight."—Langley Aerodrome, Smithsonian Report, 1900, p. 216.

FLIGHTS:

Steam model, May 6, and November 28, 1896.
Gasoline model, August 8, 1903.

Before the tablet was cast, the Wright Brothers were consulted as to the advisability of using this inscription and they, not wishing that anything discreditable to Langley should appear on the tablet, Mr. Wilbur Wright wrote a letter to Secretary Walcott, from which the following is quoted:—

"I have often remarked to my brother that Prof. Langley was ill-fated in that he had been especially

criticised by his enemies for things which were deserving of highest praise and especially praised by his friends for things which were unfortunate lapses from scientific accuracy. I should consider it both unwise and unfair to him to specially rest his reputation in aerodynamics upon the so-called Langley Law, or upon the computation which gave rise to it, as they do not seem to represent his best work. The particular computations which led him to enunciate this law are found on pages 63-67, 'Experiments in Aerodynamics.' A careful reading shows that he never actually tried the experiments of which he professed to give the result. . . . It is clear from the Doctor's statement that he never demonstrated by direct experiment that weight could be carried at the rate of 200 pounds per horse-power at 20 meters per second, nor that the power consumed decreased with increase of speed up to some remote limit not attained in experiment. He merely assumed that he could have done it by varying the experiments a trifle and based the so-called Langley Law on this mistaken assumption."

The Regents of the Smithsonian Institution adopted this suggestion and the Langley Law was not inscribed on the tablet.

The article in NATURE of November 3 states that "the Wright Brothers are equally clear in their acknowledgment of Langley's work," and gives a quotation from them to support this idea. This quotation, taken in connection with the suggestion of the writer in NATURE, may have carried to some readers the erroneous impression that the Wright Brothers acknowledged an indebtness to Langley for his scientific work. This was not the fact. The quotation given makes no reference whatever to Langley's scientific work. It is simply a generous acknowledgment by the Wrights at the time of Langley's death for the inspiration received from his faith in the possibility of human flight, and containing an expression of gratitude for information as to books on the subject of flight other than those they had already read. The Wright Brothers have also acknowledged their indebtedness to Chanute, Mouillard and others, but have always made it clear that their greatest debt was to Lilienthal.

GRIFFITH BREWER.

33 Chancery Lane, London, W.C.2.

SOME difficulty is felt in continuing a discussion of the relative merits of the great pioneers in aviation, Prof. Langley and the Wright Brothers, since they are all entitled to our esteem, and comparison seems to be unnecessary. Mr. Griffith Brewer does not appear to dissent from such a general statement, but one suspects that his enthusiastic admiration for the work of the Wright Brothers has led him to make extravagant claims.

It is very surprising to hear that "the Wright Brothers first established a scientific basis for aeroplane design," and that their laboratory measurements "covered a field many times greater than had been covered by the work of all other experimenters together." The only publication cited in support of this contention occurs in two pages of the *Century Magazine* in 1908, and readers of scientific literature in aeronautics will realise that they do not know where to look for data based on the work of the Wright Brothers. Indeed, Mr. Brewer indicates that this must be so when he says, "While in Dayton (in 1914) I was allowed to examine, with the privilege of copying, much of the personal correspondence and diaries, as well as the records of the early purely scientific work of the Wright Brothers"; apparently the work was not publicly available. Is it then strange that one should look to Langley as the scientific pioneer, since he took the normal steps of a man of science and published complete accounts of his results as he obtained them?

Mr. Brewer refers to the "Langley Law" that the faster an aeroplane be flown the less will be the power required to sustain it. He says: "The fallacy of this law is well known to all aeronautical engineers to-day, but up to 1910 this was generally accepted as Langley's chief contribution to the science of aerodynamics." The inadequacy of the law is evident now, but it is still at least partly true; in the case of the most modern aeroplanes the horsepower for flight decreases as the speed increases from the least at which support can be obtained. The increase of power required to increase the speed of the modern aeroplane above a certain limit is due to the light-weight engine, a factor which did not come into consideration in early practice. The error of unsound extrapolation outside the experience of the day was made, but only superficial observers could regard the enunciation of the law as "Langley's chief contribution" to aeronautical research.

One can only disagree with Mr. Brewer in his review of the situation and regret that this aspect of pioneer work in aviation was introduced in the tone of the paper on "The Langley Machine and the Hammondsport Trials." The point of the paper was not so much missed, as suggested by Mr. Brewer, as countered owing to the fact that the statements therein did not carry conviction. One of the articles in NATURE intimated this in the suggestion that the Royal Aeronautical Society should take up the matter and after full investigation issue an official report. The views on the Langley aeroplane expressed by Mr. Brewer cannot be accepted as final although given in all good faith.

THE WRITER OF THE ARTICLES.

Some Biological Problems.

DR. CUNNINGHAM (NATURE, February 9, p. 173) cannot be more weary of this discussion than I. It is many years since I, becoming doubtful, first tried to discover the precise meaning of certain biological key-words. To this day I have not succeeded. It has been my misfortune to encounter authoritative people who, instead of perceiving that I was genuinely puzzled, thought I might do "much harm by leading many who have no special knowledge of heredity and evolution"—*e.g.* Professors Goodrich and Bayliss—"to distrust the work of those who are engaged in research on these subjects." May I suggest that in this matter authority and regard for public opinion are out of place. Most biologists profess to know the meanings of their terms; but there is no agreement, and no definitions can be framed which cover the whole of common and accepted usage. A science which lacks a precise and significant means of expression labours under paralysing difficulties.

Dr. Ruggles Gates thinks that a variation is a character. Surely he is mistaken. When one individual varies from another (*e.g.* child from parent) the difference is revealed in a character. If this new character becomes established in the species, it remains a character; but, even colloquially, it ceases to be a variation. How then can a variation be a character? A variation cannot be thought of without a comparison, explicit or implicit, between two separate individuals; a character can always be thought of without such comparison. Evidently, then, a variation is not a character, but an unlikeness between two individuals which is displayed in a character. When we

say that a variation is innate *or* acquired we know exactly what is meant—*i.e.* that a difference between two individuals is germinal *or* somatic, a product of nature *or* nurture. For example, if B differs from A in that he has a sixth digit and a scar, he varies innately (not by acquirement) in the case of the digit, and by acquirement (not innately) in the case of the scar. But when we say that the digit itself is innate (not acquired) and the scar itself acquired (not innate) what can we mean? We are now comparing not separate individuals, but two characters of the same individual. Obviously the digit as such is no more germinal, no more a product of nature and evolution, no less somatic, no less a product of nurture than the scar. How then is the one more innate or acquired than the other? Our terms "innate" and "acquired" are now unmeaning or else they have new meanings. But, as I say, no new meanings can be thought of which cover the whole of established usage. All this would not matter were it not for its consequences.

When it is said that an innate variation is inheritable we know exactly what is meant—*e.g.* that the descendants of B will tend to reproduce the digit (will tend to differ from A) even when reared under the same influences as A. Again, when it is said that an acquired variation is not inheritable, we know exactly what is meant—that B's descendants will not reproduce his scar when reared under the same influences as A. But when it is said that innate characters are inheritable and that acquired characters are (or are not) inheritable, what is meant? Either the word inherit has now no meaning, or in this single sentence it has two directly contrary meanings—inherit when applied to innate characters, and non-inherit (*i.e.* vary) when applied to acquired characters. We are now fully immersed in that fog of words in which, except for a brief interlude in Darwin's time, biology has strayed for a century.

The trouble began in the popular notion that, like Topsy, some (*i.e.* innate) characters "just growed," while others are acquired through some influence or other and may become, through "centuries" or "generations" of experience, "innate" in the race. Lamarck formally introduced this popular notion to science. His second law has been disputed and shown to be inconsistent with the first, but the first has been accepted without question. Yet it is crammed with obviously erroneous assumptions. It is not true that "In every animal that has not passed beyond the term of its development, the frequent and sustained use of any organ strengthens it, develops it, increases its size, and gives it strength proportionate to the length of time of its employment. On the other hand, the continued lack of use of the same organ sensibly weakens it; it deteriorates, and its faculties diminish progressively, until at length it disappears." (1) No character is in any clear sense of the words more innate or acquired than any other. (2) In our own bodies are many characters—*e.g.* hair, teeth, external ears and genitals—which do not develop in the least in response to use, or atrophy in the lack of it. Only some characters develop in response to use, and only such characters atrophy in the lack of it. There is no evidence that the development of any characters in low animals is influenced by use. On the contrary, the power of so developing appears to be, relatively speaking, a late and a high product of evolution. But as to that I shall have something to say when trying to trace evolution from the physiological standpoint. (3) Lamarck's first law dimly implies that which is more clearly implied in the writings of succeeding biologists—that although all characters develop somewhat in response to use, no characters develop greatly in that way; the actual truth being that, from birth onwards, much the greater part of the growth of the higher animals is made in response to that influence.

For millions of years Nature fashions a species to develop in response to an influence (*e.g.* injury or use). The race persists because its individuals grow in that way when need arises. At long last a biologist observes such a character—*e.g.* scar, or blacksmith's muscles. For no particular reason he calls it "acquired," and supposes that evolution results from the "transmission" of such traits—a wonderful thought, for he must know that regeneration and use-acquirements are products of evolution. For half a century his fellows agree. Then some one denies not the fundamental error, not the special acquiredness of the character, but only its inheritability. Thereafter, controversy, founded in the best scholastic style on three misused words and a number of unverified assumptions, rages for half a century. Presently a majority are convinced that acquired characters are not transmissible. Thereupon some biologists devote their energies to discovering what characters are innate and therefore inheritable, and others to discovering what characters are inheritable and therefore innate. Hedged about by her extraordinary terminology, biology becomes isolated from a number of kindred sciences and studies—physiology, psychology, medicine, history, pedagogy, and the like. Of what use is it to the students of these studies to learn that a character is innate or acquired? They want to know what causes it to develop. Of what uses is it to the biologist to know how a character develops? He wants to know whether it is innate or acquired. Meanwhile many problems, mainly psychological, social, and medical, of vast importance, on which the whole future of the race depends, await solution and the driving home of the truth by the weight of scientific proof and united scientific conviction. But all these problems are too big for the subsidiary sciences. Their students are too few in number. Moreover, in every case the evidence is derived from more than one science. Only biology, which sits at the hub whence radiate all the studies that deal with life, is in a position to deal with them, and then only if it has a clear and precise medium of expression. I daresay many biologists think I am vapouring. But, if they wait, I think they may perceive a method in my madness. This much I will permit myself to say: that unless biology awakens from her long sleep, our modern civilisation is likely to smash, just as old Rome smashed and for the same reason—because there is not enough intelligence left to run a society grown very complex.

According to Dr. Cunningham, biologists bestow the descriptions "innate" and "acquired" on characters which develop in response to internal and external stimuli respectively. That is to say, "innate" and "acquired" are supposed by him to be technical terms which have meanings quite other than their ordinary dictionary meanings. But:—

(1) Before this discussion began no one ever thought of such technical meanings. On the contrary, as attested by all literature, biologists have genuinely believed that some characters are really innate and others really acquired. Hence the synonyms—germinal, blastogenic, plasmogenetic, somatic, somatogenetic, and the like—which were coined to give definition and emphasis to this belief.

(2) Light, heat, moisture, gravitation, food, injury, and the like are all external influences; and of them, the only one which is commonly regarded as evoking acquired characters is injury. On the other hand, hormones and functional activity (use) are internal influences; and since hormones act from outside the characters they influence, whereas use acts from within, the latter is the most internal of all stimuli. But use is supposed to be more especially *the* influence

which evokes acquired characters. Clearly internal, just as much as external, stimuli evoke what are called "acquired characters."

(3) As a fact, biologists when classifying characters as "innate" and "acquired" have not in practice been influenced by the kind of stimuli which have evoked them. As again all literature testifies, they have, in accordance with popular usage, called all characters which develop in response to any very glaringly obvious stimulus acquired. For example, they do not call the musculature of the child, the youth, and the ordinary man "acquired"; but they do bestow that name on the musculature of the blacksmith, though the latter develops in response to precisely the same influence. Any number of similar examples might be named.

G. ARCHDALL REID.

9 Victoria Rd. South, Southsea, Hants,
February 25, 1922.

A Rainbow Peculiarity.

EVERY one has observed a brilliantly coloured rainbow and also the secondary bow situated some distance on the outside of the primary. Is it a fact of general observation that the whole area of the inside of the primary bow is brighter than the region outside?

It was not until the winter of 1913 that this bright inner region was brought to my notice on a photograph I secured on December 1 of that year. On the morning of that day one or two heavy showers passed from S.W. to N.E., traversing the ground to the north of the Norman Lockyer Observatory. The primary bow in question was distant about one mile to the north of the observatory, as could be judged from the spot where the rainbow ended on the ground. An attempt was made to photograph the bow with a 4×5 screen focus Kodak using the ordinary Eastman film, and on development it was found that the light from the interior area of the bow had acted on the film in a much more actinic manner than that on the outside—or, in other words, the area inside the bow was brighter than that on the outside. The accompanying illustration (Fig. 1) gives a reproduction of the photograph.

FIG. 1.—Rainbow photographed on December 1, 1913.

I somewhat doubted the reality of this appearance until I had taken another photograph of a similar nature, and an opportunity occurred in December of last year.

FIG. 2.—Rainbow photographed on December 22, 1921.

On December 22 numerous showers were passing to the northward of the observatory, and I photographed three different rainbows during the morning. They were not so brilliant as that photographed in 1913, but yet sufficiently bright to record the same phenomenon. One of these photographs is reproduced in Fig. 2, and a comparison of the intensity of the distant landscape inside and outside the primary bow corroborates the previous photograph.

These photographs thus establish a fact in Nature which appears to have been rarely noticed visually. Kämtz in his "Lehrbuch der Meteorologie" (vol. 3, p. 158), a book which was published so long ago as 1836, writes on the subject as follows:—"When a rainbow with very pronounced colours is projected against a dark cloud, the sky above the first bow is darker than that underneath. If we follow the path of light in our spherical drops and remember the limiting values which have been given above, we receive none of the inner surface reflected rays from any drops which lie higher than those in which we found the maximum and which form the bright bows; lower-lying drops also send out rays from the inner back surface, and, although these more or less diverge, they tend to produce an undoubted brightness under the bow. The drops lying above the bow also send out reflected rays from their near sides, while from the drops lying under the bow we receive rays from the far side."

Following this extract Kämtz states that he has to thank Brandes for directing his attention to this phenomenon, and gives a reference to Gehler's "Wörterbuch," *Nach. Astr.*, vol. 7, p. 1324.

Flowering Dates of Trees.

REFERRING to Mr. J. E. Clark's interesting article on the above subject in NATURE of February 16, I would suggest that a consideration of the different variations of temperature between Falmouth and London will help to solve the problem. From phenological observations I have made at Falmouth for many years past, it would appear that on an average this district is earlier than nearly all other parts of England in January and February by about a fortnight, but that after those months the lead is lost and the flowering and leafing of trees, etc., are retarded by our situation being near the coast line, where the waters of the European current play such an important part in lowering the land temperatures in summer and raising them in the winter. It is not always sufficiently realised how much longer the sea requires than the land to gain its summer heat and then to lose it again. Thus we find from the records of 41 years that the mean temperature of the sea in December is 50·1°, whilst in January, February, March, and April it is less, viz. 48·0°, 47·0°, 47·3°, and 49° respectively.

The following table (1920 being taken at random) shows that in January and February our mean temperature is higher than about London, but during March, April, and markedly in May, it falls behind and it is only natural that the effect on the flowering and leafing of trees, etc., should be as described by Mr. Clark.

WILSON LLOYD FOX.

Falmouth, February 24, 1922.

Where did Terrestrial Life Begin?

IN reference to Mr. Dines's letter in NATURE of February 16, if the diurnal variations in temperature and humidity on a mountain summit in the early earth would have been smaller than at sea-level, my objection to Dr. Macfie's theory would certainly not hold. But Mr. Dines remarks that, assuming some stratification of the atmosphere, the stirring up of the lower levels might cause a temporary raising of the temperature at higher levels, which is the basis of my objection. Mr. Dines points out that if the early atmosphere had been homogeneous, mountain summits could not have been warmed by ascending air, while if the air had been stratified vertical movements would have been impossible; but that dilemma does not seem applicable to the conditions likely when the earth had just cooled down to a temperature at which life was possible.

My conception of the probable geographical conditions at the dawn of terrestrial life is that the seas would have been small, but were growing from water discharged from steam vents, which would have kept the lower air hot and saturated. Above the steam-charged layer the air temperature would have fallen quickly (as the surface would have received less heat from the interior and have lost more by radiation), so that the cooling by expansion of air rising up a mountain side would have been small and might have been largely counteracted by latent heat set forth by the condensation of moisture. Distrustful of my own capacity in thermodynamics, some years ago I asked an expert on that subject, in reference to another problem in primeval geography, whether the last condition was possible, and he replied that it was. The geographical conditions which would seem most favourable for spontaneous generation from some inorganically formed carbohydrate would be in a moist atmosphere in which the temperature would have been practically uniform. Unless those conditions held on a mountain summit, some lower position for the origin of life would seem more probable.

J. W. GREGORY.

February 20, 1922.

The Name of the Gid Parasite.

IN 1910 (U.S. Dept. of Agriculture, Bureau of Animal Industry, Bull. 125) Dr. Maurice C. Hall published a most interesting historical account of the gid parasite, a cestode worm which is exceedingly destructive to sheep. He showed that the first available specific name for the worm was *Taenia multiceps* of Leske, 1780. At the same time he rejected the familiar name *Coenurus* of Rudolphi because Goeze in 1782 had said that the parasite might be called "Vielkopf (*multiceps*)." I protested at the time to Dr. Hall that "multiceps" could scarcely be taken as a valid generic name. Goeze was not a binomial writer; he actually called the gid parasite Taenia *vesicularis cerebrina*. *Multiceps* seems to have been introduced simply as the Latin form of the common name proposed, *vielkopf*. Now, after the passage of years, I again have occasion to refer to the gid parasite and I find no ground for altering my opinion. Apparently the animal should be called *Coenurus multiceps* (Leske). The matter is important, on account of the injuries caused by the parasite, and consequent frequent references to it. I observe that Railliet and Henry (1915) and Railliet and Marullaz (1919) accept *multiceps* as a valid generic name.

University of Colorado, Boulder, Colorado.

The Weathering of Mortar.

IN regard to statements in NATURE of June 23 and July 21, 1921 (vol. 107, pp. 523 and 652) to the effect that the curious ridges and furrows which occur in mortar in walls are due to the segregation of lime, I would invite attention to a note in Proc. Dorset Nat. Hist. and Antiq. Field Club, 1906, vol. xxvii. p. xxxii, giving an account of an exhibit of mine of a series of pieces of mortar from a wall showing the early stages of the development of this phenomenon. The appearance is caused by the growth of moss in minute shrinkage cracks in the mortar, the sides of the cracks being gradually disintegrated by the roots of the moss, until the final stage of ridge and furrow is reached and the moss, not having sufficient root-hold, falls out when dry.

I may add that since then I have tested the mortar in the ridges and also some from the general body below the surface, and can find no difference in the proportion of lime contained in the two.

Cancer Research.

By DR. J. A. MURRAY.

DURING the last twenty or thirty years the above title has been very frequently the text for reviews, summaries and editorial articles, and might in other circumstances be regarded as covering an over-written subject. The wide interest taken in cancerous diseases—an interest stimulated by the apparently increasing toll of this malady which the mortality figures of the Registrar-General reveal—suggests that the editorial request for a further article on the same theme should not be neglected. Recently the general Press has contained the announcement of Lord Atholstan's offer under certain conditions of a prize of 22,000*l.* for the discovery of a medical cure for cancer, whilst this has been followed by Sir William Veno's prize of 10,000*l.* The final form in which these sums will be applied to the stimulation, and perhaps the subvention, of cancer research has probably not yet been definitely decided, but both gifts can be looked upon as concrete examples of the importance which men attach to a solution of the problem of cancer.

At the present time we have in this country two important and outstanding diseases, namely, cancer and tubercle, both of which are great destroyers of human life. The latter is certainly the more important in an economic and social sense for it attacks people at a much earlier age, but nevertheless it does not seem to have the same hold as cancer on the imagination of the public. It would almost seem as if the *spes phthisica,* the illusory hope of recovery often entertained by the almost moribund consumptive, had spread from the victim to his fellow-man. The prime cause of tuberculosis has been known for forty years, yet treatment is still very unsatisfactory; in cancer the cause is still unknown, and a wider field for investigation is presented, as well as one offering the attraction of the unknown.

Physicians and surgeons are not alone in entertaining the interest thus awakened, but share it with a wider army of pathologists, physiologists and biologists, who may regard cancer as a perverted form of growth perhaps induced by an aberrant type of metabolism. If we restrict our survey to the period of the war and the following years, we find that although research was greatly curtailed, especially in Europe, it did not cease entirely; since the war, work has been resumed and certain progress made. To-day, work is being done even in impoverished Austria, and from Japan in the East to the United States in the West, from Denmark to the Argentine Republic. Investigation into the nature of cancer is almost as widespread geographically as the disease itself.

It is at no time easy to formulate a working hypothesis for attacking a biological problem, and it is especially difficult in the case of the ill-defined one we are considering; but if the attempt be made to analyse the different lines of inquiry adopted, this might profitably be done by arranging them according to their bearing upon the theory that cancer is caused by an extraneous parasite. The parasitic theory has been in the field for many years, but from the opening of the present century it did not claim so many adherents until about ten years ago, when its advocates had their view strengthened by the discovery of a peculiar sarcoma in fowls which could be transmitted by a porcelain candle filtrate, and presumably contained one of the filterable viruses. The exact relation of this chicken sarcoma to the true neoplasms is still a matter of uncertainty, but the failure to repeat this experiment with tumours from other animals leads one to suppose that their nature is essentially different. A similar comment applies to the infective venereal tumour of dogs, a sarcoma-like growth transmitted by coitus, especially amongst bull-dogs. Here, again, it is no easy matter to define the relationship with the infective granulomata on one hand, or with the true neoplasmata on the other.

A great many of the opponents of the parasitic theory of cancer believe in the efficiency of "chronic irritation" as an actual inducer of the cancerous transformation of a tissue. By chronic irritation they usually mean a prolonged succession of chemical or physical insults to a group of cells, these insults being of a degree which does not destroy the vitality of the cells but serves to excite their powers of growth and reproduction. That cancerous disease may supervene in tissues maltreated in this way is shown in a wide variety of cases, of which there may be cited chimney-sweeps' cancer, "kangri" cancer, the cancer of X-ray workers, and the cancer developing at the site of a long-standing ulceration.

All these instances lead directly to the attempt to produce cancer experimentally, but it is only within the last few years that any measure of success has attended the experiments. The production of cancer has been most successful in rabbits and mice in which a small skin area has been painted for a period of six to twelve months with coal tar. About half the animals thus treated show tumour growth at the treated site, and the method promises to be exceedingly useful for studying the conditions affecting tumour origin. Another method of producing cancer experimentally is less straightforward than the preceding, but about equally efficacious. In this a chemical or physical agent is not applied but the irritation produced by the presence of a gross parasite is employed. The artificial infection of rats by a species of nematode, *Gongylonema neoplastica,* leads to the overgrowth of the squamous portion of the stomach and in a fair percentage of cases to the development of cancer. Sarcoma of the liver of rats can also be produced with ease by the simple expedient of infecting the animal with ova of the cat tapeworm, *Taenia crassicollis.* All three methods seem likely to further our knowledge of the etiology of the disease.

The search for the cause of cancer in a developmental (embryonic) abnormality does not appear now to command many followers; it is at best a very fatalistic line of thought, and discouraging to all but the most robust-minded.

Starting from an already established tumour, much work has been done upon observing the characters of

the growth exhibited and the nature of the differentiations displayed by the tumour cells. The discovery of the transplantability of tumours of the lower animals has provided much material for this line of research, but the many attempts made to fix on any one outstanding character of tumour cells differentiating them sharply from normal cells have been unsuccessful. As before, we are confronted with the unexplained and unco-ordinated powers of proliferation shown by the tumour cells. The discovery that animals could be rendered resistant to transplanted tumours raised hopes that it might be possible to elicit an immunity towards cancer in an animal affected spontaneously, but these hopes are now considerably abated.

A start has also been made to ascertain the food requirements, general and special, of the tumour cells, but these experiments are still too slightly advanced for us to know whether any result of positive value will be obtained.

Research into the treatment of cancer other than surgical has produced many empirical experiments and observations, but, apart from the extended knowledge of radio-therapy, nothing of importance has come to light. In the field of radio-therapy, the manner of action of the rays used, and the way in which they induce destruction of cancerous cells, still offers an unsolved problem of high importance. In conclusion, it may be predicted that progress in cancer research will in large measure be closely co-ordinated with that in the ancillary sciences.

The Mechanism of Heredity.[1]

By Prof. T. H. MORGAN, Columbia University, New York City, U.S.A.

III.

Further Relations between Chromosomes and Heredity.

IN examining the chromosomes for a stage when "crossing-over" might be possible, we turn naturally to the time when the members of each pair come together. This occurs once in the history of every germ-cell. In many accounts it has been shown that the members of each pair come to lie side by side throughout their length. Even more interesting is the fact that just prior to this union the chromosomes have spun out into long, thin threads. There are also

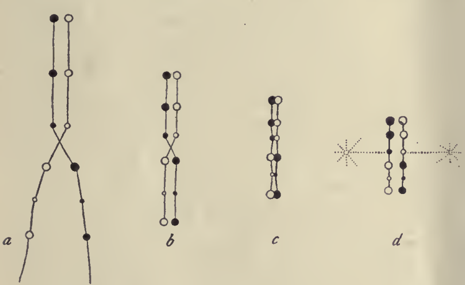

FIG. 16.

several detailed accounts showing that at this time the two chromosomes of each pair may actually twist about each other in one or more turns (Fig. 16). They then come to lie side by side and appear as a single thread that shortens preparatory to entering upon the first maturation division. Here, apparently, we find realised a condition that might make interchange possible between the members of a pair of chromosomes, for if the threads fuse where they cross each other and the ends on the same side unite, the interchange of pieces will be accomplished. From the nature of the case it would be almost impossible to demonstrate that the twisted threads do break and make new unions at the crossing point. It is true that there are certain later stages that lend, perhaps, some support to the view that breaking and reunion have occurred, as Janssens has pointed out, but it cannot be claimed that this evidence does more than give, on such an assumption, an account consistent with certain configurations he describes. Here the case must rest for the present. The genetic evidence is clear and far in advance of what the cytologist is able to supply. But, nevertheless, it is very important to find that, so far as the cytological evidence goes, it furnishes a great many of the facts essential to the kind of process that the genetic evidence calls for.

The Number of the Linkage Groups and the Number of the Chromosomes.

When Sutton in 1902 directed attention to the fact that in the behaviour of the chromosomes at maturation there was supplied a mechanism for Mendel's two laws, it was evident that the number of independently assorting hereditary characters would be limited to the number of the chromosome pairs characteristic of each species of animal and plant, provided the chromosomes remain intact from generation to generation. The integrity of the chromosome was held, in fact, by a few leading cytologists at that time, notably by Boveri, on evidence which, if not complete, was the best then obtainable. In the circumstances, the later discovery of the agreement between the number of chromosome *pairs* of *Drosophila melanogaster* and the number of its linkage groups was of paramount importance for the chromosome theory. In this species the number of known hereditary characters is so large (more than 300 in all) that this relation can scarcely be due to a coincidence, especially when the whole evidence concerning chromosomes and heredity is taken into account.

It is true, with the possible exception of the garden pea (where there appear to be as many independently

[1] Continued from p. 278.

Mendelising pairs as there are chromosome pairs, namely, seven), that this relation has as yet been established only for species of Drosophila. But it is also true that not a single animal or plant has yet been found in which the number of known hereditary groups of genes is greater than the number of chromosome pairs. It is to be anticipated that some one will before long announce such a discovery, for it is very probable that if two linked genes happen to be so far apart as to give 50 per cent. of crossing-over, they will appear to be in different groups. But such a situation need cause no alarm when (or if) it arises, and will not, of course, refute the correspondence of linkage and chromosomes, unless it can be shown that each such member belongs to a different linkage system. Furthermore, it is to be anticipated that where compound groups of chromosomes exist, such as have been described in some grasshoppers and bugs, peculiar relations are likely to be found.

The evidence from two species of Drosophila other than *D. melanogaster* should also be taken into account. In *D. obscura* Lancefield has shown that there are five pairs of independently assorting characters. There are also five pairs of chromosomes. In *D. virilis* Metz has found six pairs of chromosomes, and up to the present at least five independent loci. The fact that no crossing-over takes place in the male makes the evidence for the independence of the pairs practically certain.

Origin of Mendelian Genes.

Mendelian heredity is sometimes slightingly referred to as a particular kind of heredity dealing with characters that are due to losses of wild-type *characters*. This view ignores some significant facts and considerations. To argue that because a *character* is lost or modified there must be a corresponding loss in the *germ-plasm* is clearly a *non sequitur*. Each organ of the body is the end result of a long series of stages in embryonic development. Any change in any one of the stages would be expected to alter the end product. There are no grounds for assuming that such changes must necessarily be losses, although losses also might sometimes produce such effects. The argument has all the earmarks of reasoning by analogy.

However, the discussion need not rest any longer on philosophical grounds, since we have crucial experimental data which show that loss of a character is not necessarily due to loss of a gene. One case will suffice. In addition to the white-eyed mutant of Drosophila there are ten other eye colours that lie in the same locus. Obviously there cannot be ten kinds of absences. The only other possible explanation of ten absences would be that there were ten genes here so close together that crossing-over does not take place. Hence they appear to be in the same locus. Now, fortunately, the origin of these ten mutations is known, and shows—if they were really a closely linked nest of genes—that when the last one appeared there must have been at the same time mutation in nine other genes in order to get the results. The rareness of mutation precludes such an interpretation. Attempting to save the interpretation of recessive characters as due to absence of genes, it has been argued that perhaps only a part of the wild-type gene is *lost* when a new recessive character appears. It is, however, not obvious why the hypothesis needs to be saved. It is simpler and suffices to cover our ignorance to say that a change has taken place.

There is another question connected with these multiple allelomorphs—changes in the same locus—that is very important. Any given individual may normally have at most any two of the genes (one derived from the father, and one from the mother), but never more than two. When there are two such mutant genes present they behave towards each other in the same way as does any mutant gene towards its wild-type allelomorph. It follows that the Mendelian behaviour is not a peculiar relation of a mutant gene to a wild-type gene. It would seem, therefore, highly probable that wild-type genes behave in this way towards each other, and, in fact, where two wild types exist in Nature that differ in a single allelomorph, they are found to give a Mendelian segregation when brought together.

The discovery of a large number of mutants in the same species may be expected in time to furnish some idea of the number of hereditary genes that exist in a species, or, in other words, to tell us how many different kinds of genes *plus* the cytoplasm constitute a species. At present, even in the case of Drosophila, we are far from being able to make such a calculation. There are, however, one or two rough estimates which seem to indicate that the number of genes is more than several thousands. The upper probable limit cannot even be guessed.

How the genes bring about their effects, which are shown as modifications of the protoplasm (or by-products of it), is entirely unknown. If it seems desirable at present to limit the definition of heredity to cover only the distribution of the genes in successive generations, the result of their effects on the protoplasm becomes a problem of embryology. To many geneticists, however, no such limitation seems desirable, because it may appear that the ultimate constitution of the genes themselves can be discovered only by working backwards, through the effects produced, to the nature of the material that furnishes the first stage in the elaboration. With this pious hope I heartily agree, but in the meantime I do not think it desirable to let premature attempts in this direction interfere with clear-cut methods of research that Mendelian results supply.

Finally, the question as to whether all hereditary characters arise, or have arisen, through mutational changes in the germ-plasm similar to those found occurring to-day, can be settled only by future evidence. Guessing is scarcely worth while. One point, however, seems fairly well established—namely, that in several cases where differences in wild species have been subjected to the experimental analysis employed by geneticists for variation arising by mutation, they give the same kind of results.

Obituary.

SIR GEORGE CARTER, K.B.E.

BY the death of Sir George Carter, there passes one of the greatest figures in the shipbuilding industry of the last twenty years. He had been in ill-health for rather more than twelve months, but had not formally retired from his position of managing director of Messrs. Cammell Laird's famous shipbuilding and engineering works at Birkenhead. Sir George Carter was trained at the Royal Dockyard at Portsmouth, and furnishes another name on the list of great shipbuilders who have come from that excellent nursery, the Dockyard Schools.

Soon after completing his training at Portsmouth Sir George Carter proceeded to the well-known Tyneside firm of Messrs. Armstrong, Whitworth, and Co., where his uncle, Sir Philip Watts, was naval architect. A man of extraordinary vigour and of sound judgment, he was quickly given the important post of shipyard manager, and his tenure of this position for eighteen years witnessed the production of some very notable and epoch-making ships as well as a large extension of the firm's premises at their merchant shipyard at Walker.

Though always an important figure in the industry, it was during the last ten years that Sir George Carter came very prominently before the public, when in 1912 he became managing director of the Merseyside firm. He succeeded in extending the firm's business and premises in a remarkable manner, and when the war came in 1914 he was able to devote his whole energies to, and to utilise to the full the firm's great resources in the construction of warships.

Sir George Carter's activities were too numerous for mention in a short notice of his career, but reference must be made to the very important part he played as chairman of the Advisory Committee on Merchant Shipbuilding under the Shipping Controller in the fateful days of the early part of 1917. It was this committee that evolved the standard ship and made a supreme effort to organise the whole industry in order to simplify manufacture and increase output. Sir George also occupied many positions of importance, being a member of the council of the Institution of Naval Architects, of the Committee of Lloyd's Register of Shipping, of the Mersey Docks and Harbour Board, and of the Court of the University of Liverpool.

All those who knew Sir George Carter intimately and were familiar with his work during the war will agree that he spent himself in the service of his country and sacrificed some years of his life in its behalf.

T. B. A.

DR. H. LYSTER JAMESON.

WE regret to announce that Dr. Henry Lyster Jameson died at his home at West Mersea, Essex, on February 26, of hæmorrhage of the lungs, at forty-seven years of age. Dr. Jameson was educated at Trinity College, Dublin, where he took the degrees of B.A. and D.Sc. He spent a year at the Royal College of Science, London, and then worked at the University of Heidelberg, where he studied zoology under Bütschli. Afterwards he went to British New Guinea, where he had charge of a pearling station, and this gave him opportunities for research into the causes of pearl-formation, an investigation which he continued at the Lancashire Sea Fisheries Station in Piel, Barrow-in-Furness. There he established the parasitic theory of pearl-formation in the common sea mussel, and he extended the research later into a study of the various processes by which the orient pearl is formed, publishing a series of papers in the *Proceedings of the Zoological Society* and elsewhere. About this time his health broke down, and, threatened with pulmonary phthisis, he went to South Africa, where he was, for a time, on the staff of the Natal Education Department and, later, a lecturer at the Technical College in Johannesburg.

Some few years before the war Dr. Jameson returned to England and was appointed to a post in the Board of Education, becoming a Senior Examiner. At the outbreak of war in 1914 he was seconded for special service in the Ministry of Agriculture and Fisheries, and, later, became District Inspector for the South-Eastern Coast. At that time the slipper-limpet was becoming a pest to the oyster fisheries, and Dr. Jameson organised a system of collecting and disposing of this noxious mollusc. A very successful factory for the preparation of shell-grit from the limpets dredged up in the course of the oyster fishing was set up at West Mersea, and he was in charge of this up to the time of his death. In 1918 he became Adviser on Inshore Fisheries to the Development Commissioners and his work became largely administrative, but lately he was very active in the investigation of vitamins in molluscan shell-fish, working on this subject in collaboration with Prof. W. Bayliss.

Such was Dr. Jameson's persistent ill-health that any form of physical activity became impossible, but under this strain he developed a strong and most engaging personality and wide interests in social and economic reform movements. He was a man of great general culture, a very accomplished field zoologist, and a most lovable friend to those who knew him well. He leaves behind him a widow and two daughters.

SIR EDWARD GONNER, K.B.E.

WE record with great regret the death, on February 24, in his sixtieth year, of Sir Edward C. K. Gonner, who was for more than thirty years the Professor of Economic Science in the University of Liverpool, and whose skill and power of organisation have done much to earn for that University the high position it holds as a centre of economic teaching. The view which he entertained of the difficulty and of the importance of economic study, and which inspired him in his work, is well expressed in the address he wrote for the Toronto meeting of the British Association in 1897, as President of Section F: "This is needed by all those who, either by action, word, or vote, have a part in the direction of the destinies of a country." Again appointed President of that Section at the Australian meeting in 1914, he enforced the same moral. He published some valuable text-books on economic subjects. He served on the Royal Commission on Shipping Conferences. As chairman of the War Savings Committee for Cheshire he also rendered public service, and was appointed a Companion of the Order of the British Empire. He was promoted to a

knighthood of the same Order last year. Sir Edward Gonner's early death was due to an attack of influenza. At a time like the present when the inculcation of sound economic principles seems to be more than ever necessary, the loss of so good and practical a teacher as Sir Edward Gonner will be deeply felt.

MR. GEORGE CUSSONS.

IT is with regret that we record the death on February 10, at the age of seventy-five years, of Mr. George Cussons, the founder of the well-known firm of scientific apparatus makers of Lower Broughton, Manchester. Mr. Cussons in his early manhood gained a studentship at the Royal School of Mines, London, and upon the completion of the course became a drawing-master and also a teacher of geometry and mechanical subjects in evening classes in towns near Manchester. Having considerable mechanical skill, acquired in the course of his apprenticeship, he devised a variety of models and apparatus, which he employed effectively to demonstrate the problems arising in the course of his teaching. Finding great advantage accruing therefrom, he was induced to enter business life as a manufacturer of apparatus to be used in the demonstration of the subjects of geometry, theoretical and applied mechanics, and of physics. Among other excellent apparatus he designed and patented a much-improved Atwood's machine to demonstrate the laws of falling bodies. His firm gained well-deserved repute among Technical Institutions for the excellence and adaptability of its apparatus.

Mr. Cussons, whilst he was a student at the evening classes of the Owens College, Manchester, made the acquaintance of Osborne Reynolds, the eminent Professor of Engineering at the College, and brought to his notice certain models for use in Descriptive Geometry. He suggested various improvements which were adopted, and the models were exhibited at the National Health Exhibition of 1884, where they gained a medal for excellence. Since that time the firm has been awarded medals for the superior character of its apparatus at exhibitions held at home and abroad, and has supplied scientific equipment to practically every country in the world. It furnished a large number of models for geometrical and mechanical drawing, together with a considerable equipment, for the extensive mechanics laboratory of the Manchester College of Technology, which have proved of eminent service. Mr. Cussons was in close touch with all the principal science institutes, and was always ready to discuss any new suggestions for apparatus, and to place his practical training and his knowledge of the teaching of mechanical and physical science at the service of those concerned.

THE death occurred on January 28, in his 52nd year, of Dr. Charles Baskerville, who had been professor of chemistry at the College of the City of New York since 1904. Dr. Baskerville had previously occupied a similar post at the University of N. Carolina. He did notable work on the rare earths, and carried out many investigations in the chemistry of anæsthetics. His inventions included processes for refining oils, hydrogenation of oils, plastic compositions, reinforced lead, etc.

WE notice with much regret the announcement of the death on March 3, at fifty-five years of age, of Prof. Benjamin Moore, Whitley Professor of Chemistry in the University of Oxford.

THE *Chemiker Zeitung* reports the death on February 13 of Prof. Theodor Liebisch, of the University of Berlin, well known for his work on physical crystallography, especially in the department of crystal optics.

Current Topics and Events.

A NATIONAL tribute to the memory of Sir Ernest Shackleton took the form of a special service in St. Paul's Cathedral at noon on March 2. The service was conducted by Dean Inge and the Cathedral clergy and was short and simple but impressive and of great beauty. It included some sentences from the Burial Service, the twenty-third Psalm, the lesson from 1 Corinthians xv., the anthem "Thou wilt keep him in perfect peace," and two special hymns, "Eternal Father, strong to save" and "For all the saints who from their labours rest." The soft beauty of the perfect music was followed with striking effect by the shrill sounding of "The Last Post" by the boys of H.M.S. *Worcester*. It was impossible amid the splendour of the ceremonial and the distinguished congregation representative of the most refined civilisation not to picture in contrast the rough chapel on South Georgia and the toil-stained whalers who surrounded Sir Ernest Shackleton's grave, and the little *Quest* carrying on the mission on which he perished, tossing in the huge waves of the Southern Ocean or beset by the Antarctic ice. The congregation at St. Paul's included the widow and three children of the explorer, several of his sisters and other relatives, representatives of the King, Queen Alexandra, the Prince of Wales, the Duke of Connaught, the Colonial Secretary, the First Lord of the Admiralty, the Trinity House, and the diplomatic representatives of Norway, Denmark, Portugal, Argentina, and other countries. The Royal Geographical Society was represented by its President, a large number of the Council, and the principal officials, and many other societies and institutions sent representatives. Amongst those with special interest in the Antarctic regions were Mr. John Q. Rowett, Sir John Scott Keltie, Dr. H. R. Mill, Dr. H. O. Forbes, and a strong muster of Sir Ernest's old comrades, including Captain C. W. R. Royds, R.N., and Mr. L. C. Bernacchi of the *Discovery* expedition, Capt. W. Colbeck of the *Morning*, Sir Philip Brocklehurst of the *Nimrod* expedition, Mr. J. M. Wordie, Mr. Greenstreet, and Mr. Rickenson of the *Endurance* expedition, and Mr. Mason, who had sailed on the *Quest*, but had to return on account of his health. No doubt others were present who were not recognized in the great congregation.

MR. CAMPBELL SWINTON gave some very interesting reminiscences at one of the meetings recently held to celebrate the Jubilee of the Institution of Electrical Engineers. In particular he recalled some of the experiments carried out in 1879 by David

Hughes, whose widow, who died recently in America, has bequeathed some of his notebooks to the British Museum. These have been examined by Mr. Swinton. They prove that Hughes undoubtedly noted some of the effects now known to be due to high-frequency waves. He used a small spark coil as a generator, and a Bell telephone and a battery generally connected in series with a microphone as a receiver. The microphone apparently acted sometimes as a coherer and possibly sometimes as a thermocouple rectifier. He received signals up to distances of about a hundred yards. He noted that the effects produced were very uncertain at the distance of half a mile. When he earthed one or both ends of his transmitting and receiving circuits he got enhanced results. It has to be remembered that all this was done about nine years before Hertz's memorable discoveries. Hughes, however, seems to have had no conception that he was dealing with electromagnetic waves. He thought that the effects were due to electric conduction through the air. In a letter to *The Electrician* on May 5, 1899 (vol. xliii. p. 40), Hughes himself describes his experiments. It appears that he showed his experiments to a number of leading men of science in 1879 and was profoundly discouraged by their comments on them. In particular Sir George Stokes stated that the effects were due to ordinary electro-magnetic induction. It would be interesting to speculate what might have happened had they encouraged him to proceed with his researches. But in any case a great deal of further experimental work would have had to be done before the art of radio-telegraphy was achieved.

SIR ROBERT HORNE, Chancellor of the Exchequer, in the House of Commons on March 1, surveyed the proposals put forward by the Geddes Committee on National Expenditure, and indicated the general views of the Government concerning some of them. The two items which in the main make up the "cut" of £18,000,000 recommended by the Committee as regards education are the reduction of teachers' salaries and the exclusion from school of children below the age of six years. The Government has decided that neither of these proposals can be put into operation. The reductions adopted amount to £6,500,000 instead of the £18,000,000 recommended by the Geddes Committee. It is proposed that teachers should contribute five per cent. of their salaries towards their superannuation fund, and this will bring in a sum of more than £2,000,000. The Department of Mines is to become an integral part of the Board of Trade, and the Minister who at present acts as secretary of the Department is to be one of the under-secretaries of the Board. The Forestry Department is to be carried on and will not be abolished as recommended by the Geddes Committee. As to agriculture, the Government has decided that the grant made available by the Corn Production Appeal Act cannot be used to make up the reduction upon education and research recommended by the Geddes Committee, but has to be additional to the amount already devoted to these purposes.

THE first Scientific Reunion of the Natural History Museum Staff Association for the current year, which took place on March 1, attracted an exceptionally large attendance. Many interesting exhibits were on view, among which may be mentioned the following: Fine group of Alaskan Bighorn Sheep, consisting of a male, female, and young, recently presented to the Museum by Mr. T. R. Hubbock; selection of the mammals, birds, and insects collected by the Mt. Everest Expedition in 1921; original plaster cast prepared by Mr. F. O. Barlow of the brain cavity of the Rhodesian Skull; model made by Mr. G. C. Robson of the curious triplicate respiratory mechanism in the Ampullariidæ; specimens and model of the gigantic frogs which swallow crabs and even small mammals whole; the flower-mimicking mantid from East Africa; Cichid fishes from Lake Victoria and certain Crustacea illustrating mutation; samples of wool treated with lichen dyes with or without mordants; specimen of *Orites excelsa* from Australia showing deposit of aluminium succinate in the cavities of the wood; a meteoric stone, weighing 4½ lbs., one of the hundred that fell on October 16, 1919, at Bur-Gheluai, Bur-Hagala District, Italian Somaliland; and a series of minerals from Zermatt. Messrs. Watson & Sons gave a demonstration of their most recent microscopes and ancillary apparatus.

THE Air Ministry announces that the Civil Aviation Advisory Board, the creation of which was announced by the Under-Secretary of State for Air at the recent Air Conference, has now been set up with the following terms of reference:—"To advise generally on the development of Civil Aviation and to report upon any specific point which may, from time to time, be referred to the Board by the Secretary of State for Air." The constitution of the Board is as follows:—The Under-Secretary of State for Air (Lord Gorell), chairman; The Controller-General of Civil Aviation, Air Ministry (Major-General Sir Frederick H. Sykes); The Director-General of Supply and Research, Air Ministry (Air Vice-Marshal Sir W. G. H. Salmond); representatives of General Post Office (Brigadier-General F. H. Williamson), Air League of the British Empire (Major-General Sir W. Sefton Brancker), Association of British Chambers of Commerce (Mr. Edward Manville), Federation of British Industries (Mr. H. James Yates), Lloyds (Lieut.-Colonel Sir Frederick Hall), Royal Aero Club (Brigadier-General Sir Capel Holden), Royal Aeronautical Society (Lieut.-Colonel Mervyn O'Gorman), Society of British Aircraft Constructors, Limited (Sir Henry White Smith). The secretary of the Board is Mr. F. G. L. Bertram, Air Ministry.

WE learn from *Science* that Dr. I. C. White—who has been State Geologist of West Virginia since 1897, and is distinguished for his contributions to the geology of coal and petroleum—and Mrs. White have given to the University of West Virginia and the city of Morgantown 1911 acres of Sewickley coal, situated in Marion County. It is estimated that

the tonnage of the acreage will be approximately 15,000,000, and should yield at least 800,000*l*. over a period of years, of which the city and the University will have equal shares. The income which the University will derive from the gift is to be devoted solely for equipping and maintaining a geological department in the State University in the city of Morgantown, West Virginia. Western Reserve University has also received a noteworthy gift from Mr. Samuel Mather, of Cleveland, who has announced that he will provide funds for the erection of the new building of the School of Medicine. The estimated cost of this is about 506,000*l*.

AT a meeting of the council of the British Medical Association held on February 15, the gold medal of the association was awarded to Sir T. Clifford Allbutt, Regius Professor of Physic in the University of Cambridge, for his long and distinguished services to the profession and the association, and in commemoration of his five years' presidency of the association in the time of the great war, 1916–1921. In proposing the award, the Treasurer of the Association, Dr. G. E. Haslip, said that on all the three grounds for which the medal was customarily awarded no more fitting recipient could be found. Alike for his scientific attainments, for the measure in which he had enhanced the honour and dignity of the profession, and for his devoted services to the British Medical Association, Sir Clifford Allbutt richly merited this distinction. It was agreed that an engrossed testimonial, stating the grounds of the award, should be prepared and presented, together with the medal, at the Glasgow meeting in July next.

WE have received from The City Sale and Exchange, 81 Aldersgate Street, E.C., the sole British agents, the catalogue of microscopes and photomicrographic apparatus of the Koristka Optical Co., Milan. Koristka microscopes are obtainable for all classes of work; the objectives have a reputation for being of the highest quality, and are of the apochromatic, semi-apochromatic (fluorite), and achromatic types. A binocular form and a light aluminium travelling stand are supplied. The photomicrographic apparatus includes both vertical and horizontal forms, half-watt lamps of 100-300 candle-power constituting the illuminant. Dark-ground condensers, blood-counting apparatus, microtomes, hot and mechanical stages are also listed. The microscope stands included in the catalogue can be supplied from stock, and are approximately only half recent German prices for similar models.

THE Annual Conversazione of the Institution of Electrical Engineers will be held at the Natural History Museum, South Kensington, S.W., on Thursday, June 29.

THE Guthrie Lecture of the Physical Society will be delivered on March 24 at 5 o'clock, at the Imperial College of Science, by Prof. N. Bohr, who will take as his subject "The Effect of Electric and Magnetic Fields on Spectral Lines."

THE Chemical Manufacturers' Sub-Section of the London Chamber of Commerce, at a meeting held on February 28, unanimously adopted a resolution, "that this meeting is of opinion that the Safeguarding of Industries Act is of great potential value, and records its conviction that the establishment in this country of a Fine Chemical Industry is of the utmost national importance."

AT the meeting of the Royal Geographical Society on March 6 the president announced that all the members of the Mount Everest Expedition have now left England, and General Bruce with his two assistants from the Gurkha Regiments of the Indian Army, Captain Geoffrey Bruce and Captain Morris, must be by this time at Darjeeling making preparations for the start of the expedition at the end of this month. They will be especially concerned with the two most important matters, firstly, the organisation of the special corps of Himalayan coolies enlisted from Nepal, and the borders of Sikkim, and Tibet, and, secondly, with transport arrangements which will require very careful and methodical planning, for the expedition is larger this year than last, and is more fully equipped.

THE following were elected at the annual general meeting of the Geological Society on February 17:—*President*: Prof. A. C. Seward; *Vice-Presidents*: Prof. E. J. Garwood, Mr. R. D. Oldham, Dr. G. T. Prior, and Dr. H. H. Thomas; *Secretaries*: Mr. W. Campbell Smith and Mr. J. A. Douglas; *Foreign Secretary*: Sir Archibald Geikie; *Treasurer*: Mr. R. S. Herries; *Other Members of Council*: Mr. F. N. Ashcroft, Dr. F. A. Bather, Prof. P. G. H. Boswell, Prof. W. S. Boulton, Mr. T. C. Cantrill, Dr. J. S. Flett, Mr. J. F. N. Green, Dr. F. H. Hatch, Prof. O. T. Jones, Mr. W. B. R. King, Prof. S. H. Reynolds, Sir Aubrey Strahan, Prof. W. W. Watts, and Mr. H. Woods.

AT the annual general meeting of the Association of Economic Biologists held on February 24, the following officers and council were elected for the year 1922:—*President*: Prof. E. B. Poulton; *Vice-Presidents*: Prof. V. H. Blackman, Dr. G. A. K. Marshall; *Treasurer*: Dr. A. D. Imms; *Editors*: Dr. Wm. B. Brierley (Botany), Mr. D. Ward Cutler (Zoology); *Secretaries*: Dr. Wm. B. Brierley (General and Botanical), Dr. J. Waterston (Zoology); *Council*: Prof. V. H. Blackman, Dr. G. A. K. Marshall, Dr. S. A. Neave, Dr. W. Lawrence Balls, Mr. F. T. Brooks, Dr. E. J. Butler, Dr. E. J. Russell, Prof. J. Percival, Dr. W. F. Bewley, Mr. A. W. Bacot, Dr. J. W. Munro, Mr. A. B. Bruce.

ON Thursday, March 16, Dr. P. Chalmers Mitchell will begin a course of two lectures at the Royal Institution on "The Cinema as a Zoological Method." The Friday evening discourse on March 17 will be delivered by Prof. A. P. Laurie on "The Pigments and Mediums of Old Masters," and on March 24 by Prof. F. G. Donnan on "Auxiliary International Languages."

Our Astronomical Column.

SATURN.—This planet is now very favourably situated for telescopic study. The luminous rings are now only slightly inclined, as seen from the earth, and present but a small extent of surface and detail. The ball, however, with its various dusky bands and bright zones of different intensities, will furnish interesting features under high magnifying powers. Occasionally, white spots and other irregularities are to be seen in the belts, and markings of this kind are important and should be utilised for redetermining the rotation period. Mr. W. F. Denning points out that Saturn is akin to Jupiter in presenting a number of surface currents which differ considerably in their relative velocities. In 1903 a number of light and dark spots became visible in the north temperate region of the planet, and these indicated a rotation period of 10 hours 37 minutes and 52 seconds.

Saturn will be in opposition to the sun on March 25, and situated at a distance of 794 millions of miles from the earth.

METEORIC FIREBALLS.—A magnificent fireball is described as having passed over the southern hemisphere on January 11 last. Its flight was witnessed from the Liverpool liner *Vauban*, which arrived at New York on February 20. The fireball is described as being as large as the full moon and moving very slowly from 10 degrees above the western horizon to the eastern horizon. It occupied three and a half minutes in its flight and all the while emitted a blaze of light sufficiently powerful to illumine the sea and ship in an extraordinary degree.

On February 17, at 11·32, a brilliant meteor was observed from many places, including London, Barnet (Herts), Stowmarket, Droitwich, and Scunthorpe, Lincolnshire. As seen from places not remote from the object it appeared to be many times brighter than Venus, and its flight was fortunately witnessed by several observers who apply themselves to celestial studies, including Mr. A. King, Mr. J. P. M. Prentice, Mr. A. N. Brown, Mr. Gheury de Bray, and others. Computation shows that the meteor had a radiant at about $125° + 13°$ in Cancer, and that its height was from 62 to 29 miles from over Yarmouth to Winchester, Hants. Its luminous course extended over 41 miles and its velocity was 14 miles per second. It is remarkable how many fireballs displaying exceptional characteristics have appeared during the period from February 7 to 22 in different years.

COMPARISON OF SPEED OF BLUE AND YELLOW LIGHT.—*Harvard College Observatory Bull.* No. 763 contains an investigation of the difference in the times of the phases of the short-period variables in the globular cluster Messier 5 in Libra, as determined from photographic plates sensitised for blue and yellow light respectively. On the average the times were later in the blue light by 35 seconds, with a probable error of 70 seconds. The distance of the cluster was found by five different methods to be about forty thousand light-years, making it follow the Hercules cluster, Messier 13, as the second in nearness of those north of the equator. Accepting this distance, the speeds of blue and yellow light in the intermediate space do not differ by more than one part in ten thousand million as a maximum possible. Since any absorbing medium would cause the speeds to differ, this affords an upper limit to its amount.

THE ILLUMINATION OF THE ECLIPSED MOON.—The *B.A.A. Journal* for January contains an important article by L. Richardson discussing the action of the terrestrial atmosphere in refracting sunlight on to the eclipsed moon. Tables and diagrams indicate the amount of refraction of light at various heights above the earth. The values at heights of 0 km., 10 km., 20 km., 30 km., are 68′, 22′, 5′, and 1′ respectively; thus to reach the centre of the shadow the sunlight has to pass fairly near the earth's surface, and high mountains or clouds would intercept a good deal of it; an irregularity in the outline of the shadow in the eclipse of 1888 was plausibly attributed to cloud in the Amazon basin, or else to the Andes. The strange distortion that the sun would undergo to an observer on the moon is described.

The author deduces from theory that the centre of the shadow should be slightly brighter than the surrounding regions, and finds some support in the observations of May 1920. He constructed a model lens of concave section in printers' roller composition, with an opaque disc in the middle; when this was placed over a source of light, the brilliant ring could be seen round the dark disc, also the increase of illumination near the centre of the shadow. The bluish or greenish fringe often seen in the outer parts of the shadow is explained by stating that the sunlight that has passed high above the earth's surface would be much less reddened than that which passed low down. It is also pointed out that the varying distance of the moon from the earth is an important factor in altering the illumination in different eclipses. When the moon is in apogee it is further from the earth's "black shadow," and gets more light. After allowing for these factors, and for the mountain ranges that lie along the earth's terminator, the illumination of the moon should afford a useful index of the clearness of the zone of atmosphere that lies near the terminator.

PARALLAXES AND PROPER MOTIONS.—Mr. Van Maanen deals with this subject in *Contributions from Mt. Wilson Observatory*. No. 204 contains two important investigations, the first being a set of parallax determinations of specimen objects of various types made with the 60-inch reflector. The terms to reduce to absolute parallax have been derived from comparison with the spectroscopic parallaxes of Adams, etc. The mean parallax of 11 planetary nebulæ is of the order of 0·01″, the mean absolute magnitude is 8·4, and the mean diameter 0·06 light-year. Two Cepheids give small parallaxes of the same order as those found by Shapley from the proper motions; T Cassiopeiae, a long-period variable, has the considerable parallax 0·027″; its absolute magnitude varies from 3·9 to 9·7; two stars, Boss 500 and RR Lyræ, are notable for their high velocities, each about 200 km./sec., their absolute magnitudes being near 0; the value 0·019″ found for Nova Aquilæ is nearly the same as the accepted value for Nova Persei, 1901, while Campbell's hydrogen-envelope star (type O) and Boss 3322 (type N) are assigned parallaxes of 0·005″ and −0·002″. The radial velocity of the double cluster in Perseus is found to be −40 km./sec. and its proper motion +0·003″ in R.A. and +0·003″ in Decl. These values are so small that it is impossible to pick out cluster stars with certainty unless they are bright enough to permit their radial velocity to be determined. Tables are given of the individual motions and magnitudes of over 1500 stars.

Research Items.

THE TABOO OF WOMEN AMONG GYPSIES.—The *Journal of the Gypsy Lore Society*, now happily revived with good prospects of success, publishes in its opening number an article by Mr. T. W. Thompson on "The Uncleanness of Women among English Gypsies," which brings us back, in this England of ours, to savage taboos which Sir James Frazer has copiously illustrated in the "Golden Bough," and reminds us that the Gypsies are a foreign, oriental race established in our midst. Women, not only at special periodical seasons, are treated as impure. Gypsies will destroy any piece of crockery or any cooking utensil touched by a woman's skirt: no woman may walk over a stream or spring from which drinking water is taken, lest it may become defiled: and this power of contamination without contact applies to things like crockery: "Suppose now," said a girl, "my mother or one'm the girls had stepped over the tea-things as we was getting our teas, d'ye think my father'd ha' eaten another bite?" Women engaged in cooking never touch "red meat"—beef, mutton, or liver—but roll up their sleeves and put the meat into the pot with a fork. Men object to women using for washing up the crockery the soap they use for washing themselves. The article deserves consideration as describing a remarkable survival of taboo among a civilised race.

THE TOMB OF CONFUCIUS.—The *Museum Journal*, issued by the University of Philadelphia (vol. xii., No. 2), is devoted to an article by Mr. C. W. Bishop on "Shantung, China's Holy Land," and the tomb of Confucius. The cult of T'ai Shan, holiest of mountains, belongs to Taoism, the real creed of the common people, contrasted with that of Confucius, whose teachings represent the ideals of character and conduct of the ancestor-worshipping feudal aristocracy to which he belonged. There is also a goddess of T'ai Shan, but the most striking fact about the religion of China in feudal times is the entire absence of female divinities. Some forty miles south of the holy mountain, at Chu'u-fu, is the tomb of Confucius, a splendid temple within which is the gigantic seated figure of the sage, arrayed in royal robes, and round him statues of his principal disciples. The cemetery, said to be thirteen miles in circumference, contains tens of thousands of the graves of his descendants, perhaps the most wonderful graveyard in the world, continuously occupied by the descendants of a single man for more than two thousand years. The excellent photographs accompanying the article enable us clearly to realise this Chinese Holy Land.

NATURALISTIC ART IN EGYPT.—Under the heading "A New Chapter in the History of Egyptian Art," in the February issue of *Discovery*, Dr. A. M. Blackmann describes a new development of naturalistic art found in the tombs of the barons of Cusae, the modern Kusiyeh, about 200 miles south of Cairo. It is possible that this school of art did not originate locally, but at Heracleopolis Magna, the capital during the Ninth and Tenth Dynasties, which lasted from about 2500 to 2220 B.C. There is nothing quite so realistic and vigorous in the art of Memphis as the Cusite sculptor's representations of the lion catching a bull by the muzzle, the hartbeests, antelopes, and gazelles pursued by the hounds, and, more wonderful still, the tense, nervous figure of the noble hunter, raising himself on the toes of his right foot as he leans forward to discharge an arrow from his bow at the flying deer. Equally remarkable are the figures of two fellahin binding a bundle of papyrus reeds, the typical hulking Upper Egyptian yokels, the butt of the town-bred clerk in a coffee-house. Dr. Blackmann's review of this notable chapter in the art of Egypt is in every way to be commended.

MOUNT EVEREST MAPS.—During the Mount Everest expedition of last year Major Morshead and his plane-tablers mapped the whole country traversed on a scale of 4 miles to 1 inch, with the exception of the area within 10 miles of Mount Everest, which was surveyed photographically by Major Wheeler. On the return of the expedition this map was rapidly reproduced in colours by the Survey of India. The *Geographical Journal* for February contains a reduced reproduction on a scale of 1 : 750,000 of Major Morshead's map in outline, time being insufficient for the preparation of a hill shaded or hachured plate which has now been taken in hand. On this sheet the area around Mount Everest has not been taken from Major Wheeler's photographic survey, which did not reach London in time, but has been filled in by a map constructed at the Royal Geographical Society from panorama photographs. The positions of certain stations east and west of the mountain were resected from the few peaks the positions of which had been triangulated from the plains of India. When these stations were fixed other points could be intersected, and a framework was thus constructed on which the topography was sketched from photographs. This map is also reproduced, but on a scale of 1 : 100,000.

NEW SURVEYS IN KERGUELEN.—Considerable additions to the chart of Kerguelen were the outcome of Capt. R. Rallier du Baty's expedition in the *Curieuse* in the southern summer of 1913–14. Previous surveys of the coasts were very incomplete in many parts and little of value had been done since the visit of the *Challenger* in 1873. Capt. du Baty's work, the publication of which was delayed by the war, now appears in *La Geographie* (January 1922) in a revised large-scale chart of Kerguelen, on which many new soundings appear, and two sheets of harbour plans. Six harbours were surveyed in detail, including Port Curieuse, an unexpected discovery on the smooth storm-beaten west coast. Three other harbours were partly surveyed. The charts are admirably reproduced in colour. Some meteorological data for six months are appended to the paper.

NUCLEAR DIVISION IN OPALINA.—Prof. R. W. Hegner and Dr. Wu (*American Naturalist*, vol. 55, pp. 335–46, 1921) have analysed the relation between growth and nuclear division in the well-known multinucleate ciliate Opalina, from the frog's rectum, based on the study and measurements of 455 specimens. The investigation was undertaken with the view of affording further evidence on the nucleo-cytoplasmic relation theory, according to which an increase in the amount of cytoplasm as compared with the amount of nuclear material furnishes the stimulus which initiates nuclear division. The multinucleate condition and the absence of cell-walls make Opalina a favourable object for such study. By comparing the area of specimens in various stages with the number, size, and state of division of the nuclei the authors have been able to determine approximately the amount of increase of cytoplasm which stimulates nuclear division in Opalina. Nuclear

division in this multinucleate organism is not synchronous; one nucleus is usually stimulated to divide before the others, and this division is, for the time, sufficient to re-establish the normal relations between nuclei and cytoplasm.

VARIATIONS IN ORGANS OF AURELIA.—It has long been known that considerable variation occurs in the number of radial canals and tentaculocysts in Aurelia, but only recently has investigation been made as to whether the ephyræ produced by individual strobilæ were always normal, or, if abnormal, were similar in their abnormalities. Mr. J. W. Low has published (Proc. Roy. Phys. Soc. Edinburgh, vol. 20, pp. 226–35) an account of his observations on twenty-seven productive strobilæ, each of which was kept in sea-water in a separate vessel. The ephyræ were examined in the order in which they were produced. The largest number of ephyræ given off by one strobila was twenty-eight; the average production per strobila was about ten, and the total number of ephyræ examined was 278, of which 90 showed major or minor abnormalities. Six of the strobilæ produced only normal ephyræ having the usual eight arms and tentaculocysts, four pairs of gastric filaments, and four mouth-lappets. The remaining strobilæ produced ephyræ some or all of which exhibited departures from the normal. The same strobila may give rise to normal ephyræ and to ephyræ having more or less than the normal number of arms, and in particular cases there was found to be abrupt discontinuity, *e.g.* from a four-rayed to a twelve-rayed form. The extremes of variation were represented by three-rayed and fourteen-rayed examples.

MICROSCOPE OBJECTIVES.—The problem of improving the design of microscope objectives in the near future has been taken up seriously in the last few months, and three suggestions have been made for the more accurate measurement of the errors to which such objectives are subject. It is rightly felt that better methods of testing must be introduced before the objectives themselves can be improved. Mr. Martin at the November meeting of the Optical Society suggested a modification of the Hartman test by transmitting the beam from the objective through separate small holes in a screen; Mr. Twyman in the November number of the *Philosophical Magazine* suggested a modification of his interference method, and Dr. Hartridge in October showed to the Cambridge Philosophical Society the curves he had obtained by a third method. He restricts the beam entering the objective to a small area and determines by means of a micrometer the lateral change of position of the image of a small object. The change is reduced to unit magnification and plotted against the portion of the aperture used, expressed as a fraction of the numerical aperture of the objective. The shape of the curve obtained gives the curvature of the field, and the magnitude of the spherical and chromatic aberrations present.

TREATMENT OF SURRA IN CAMELS.—Antimony salts such as tartar emetic are frequently curative for diseases caused by protozoal and other animal parasites, *e.g.* in oriental sore and kala-azar caused by Leishmania, bilharziasis caused by a fluke (Schistosomum), etc. Capt. H. E. Cross finds that injections of tartar emetic cures camels affected with surra, a disease caused by a trypanosome. Different methods of administration were tried, and of 51 animals treated, 31 were cured (Dept. of Agriculture, Punjab, *Veter. Bull.* No. 2 of 1920).

ENZYME ACTION AND X-RAYS.—In the *Archives of Radiology and Electrotherapy* for January (No. 258) Mr. R. D. Lawrence records experiments on the effect of X-rays on enzyme action. The diastatic ferment of human blood and urine was chosen for the investigation. Radiation was performed with a Coolidge tube at 9 inches from the anticathode, with a $5\frac{1}{2}$-inch gap and unfiltered radiation at 2 milliamperes in the secondary. The radiation was carried out for from 1 minute up to 20 minutes. In no case had the radiation any effect on the enzyme action.

ANTI-OXIDATION.—During the study of the changes undergone by acrolein on long standing, it was noted by C. Moureu and C. Dufraisse that the spontaneous oxidation of this substance by an "Autoxidation" was influenced in a very marked manner by traces of impurities. Further investigation of this process (*Comptes rendus*, January 30) led to the unexpected discovery that the autoxidation of a large number of substances is prevented by the presence of certain bodies, named by the authors anti-oxidisers (*anti-oxygènes*), and this property is connected with the presence of the phenol group. Thus, the oxidation of benzaldehyde is prevented by the addition of a twenty-thousandth part of hydroquinone. Hydroquinone, pyrocatechol, and pyrogallol are especially active in preventing oxidation; ordinary phenol, resorcinol, guaiacol and the naphthols also act as anti-oxidisers, but the proportions required differ in each case. As an exception, phloroglucinol is without action, and in this connection it is recalled that phloroglucinol often reacts as a ketone. In the presence of a suitable proportion of an anti-oxidiser, furfurol remains colourless, acrolein gives no precipitate of disacryl, styrolene gives no resin on standing, linseed oil exposed in thin layers to air retains its fluidity for three years, fats (including butter) do not go rancid. Mineral substances, such as sodium sulphite and hyposulphite, are sensitive to the action of anti-oxidisers. The authors also consider the bearing of these facts on biology: phenols are fairly common in plants, generally absent in animals. It was found that the action of haemoglobin was not affected by phenolic anti-oxidisers.

THE EFFECT OF MOISTURE CONTENT UPON THE EXPANSION OF CONCRETE.—Bulletin No. 126 of the University of Illinois contains the results of a series of experiments upon the expansion of concrete carried out by Mr. T. Matsumoto, who has had some years of experience on harbour works at Formosa. The temperature coefficient of expansion of concrete is about the same as that of steel, so that these materials expand or contract together on heating or cooling. Concrete expands when it absorbs moisture and contracts when it is dried; the contraction causes stress in the concrete unless it is permitted to take place freely, and this stress appears to be not as small as is generally supposed. In reinforced concrete, the contraction may set up stresses in the steel which may reach the usually accepted working stress of steel when the reinforcement is less than 1·5 per cent. With 1 : 2 : 4 concrete and reinforcement greater than 1·5 per cent., shrinkage may produce stresses in the concrete approximating to its ultimate tensile strength, and such concrete is liable to develop cracks unless proper provision is made. The author does not consider that reinforced concrete is likely to be a durable material in places where a corrosive influence on steel, such as sea air, is active, unless proper protection against shrinkage cracks is made.

Ewing's Theory of Magnetic Induction.

AT the Royal Society of Edinburgh on February 20, Sir J. Alfred Ewing read a paper on "Models of Ferromagnetic Induction," giving a detailed account of his most recent work in magnetism.

In this paper Sir Alfred Ewing develops the theory of magnetic induction put forward by him in 1890, and discusses the reasons which have led him to modify the theory in an important particular. The theory was based on Weber's conception that a substance capable of strong magnetisation, such as iron, owes its magnetic quality to the presence within it of ultimate magnetic particles capable of being turned, and that the process of magnetising consists in compelling these particles to face more or less completely in one direction. When all the Weber particles are facing one way the iron is magnetically saturated.

What the author showed in 1890 was that the control under which the Weber particles turned was a magnetic control, and that in turning they fell over from one position of stable equilibrium to another, through an unstable phase, thereby producing the phenomena of magnetic hysteresis. This fundamental feature of the theory is retained but the author has now abandoned his further idea that the control of the particles was due simply to their mutual magnetic forces, acting from atom to atom, because a quantitative examination of the forces produced in that way has convinced him that other forces are also involved. These other forces are those which exist within each individual atom, between the Weber particle and the rest of the atom. We now know the atom to be a very complex whole, comprising many moving electrons. In a substance such as iron each atom contains a Weber particle—a thing that turns under the influence of an external magnetising force. It is not the atom as a whole that turns, but only a part of it. According to the author's view there is magnetic control exerted between the part that turns and an outer shell which is held fixed in relation to neighbouring atoms. He now shows that all the characteristics of the magnetising process can be accounted for on this basis, and may be reproduced by means of illustrative models.

FIG. 1.

The first part of the paper is a study of the equilibrium of pivoted magnets, undertaken with reference to the author's model of 1890, in which the Weber particles were represented as rows of little magnets controlling one another by their mutual forces only. It is shown that this model fails quantitatively because when the magnets are placed near enough together to give the correct form to the curve of magnetisation, in its several stages, the deflecting force which is required to break up the row is enormously greater than that which suffices to produce strong magnetisation in iron. Iron acquires only about one per cent. of its magnetism of saturation during the first or quasi-elastic stage in the deflection of the Weber particles, before irreversible turning sets in. This means that the magnets of the old model had to be set with so small a clearance between them that the stability of the row was far too great. In the new model the stability can be reduced to any desired extent, for it depends on the balance of attracting and repelling forces due to the action of opposite portions of the outer shell of the atom on the Weber particle within.

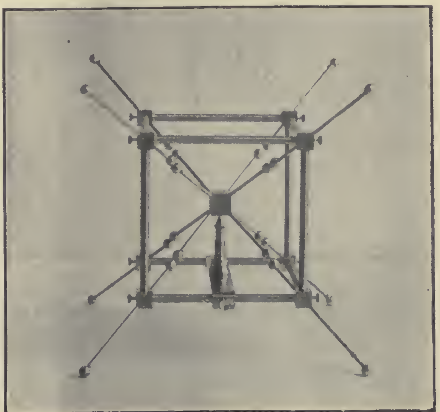

FIG. 2.

Several forms of the new model were exhibited, some with pivoted magnets to represent the Weber particles and fixed magnets to represent the controlling portions of the atomic shell. Thus in the model of Fig. 1 a pivoted magnet in the centre turns between four fixed magnets all of which present towards it poles of the same name. In the model which is shown in Fig. 2, the Weber particle is a group of eight magnetic poles, turning as a whole within a group of eight fixed magnets. The arrangement is a cubically symmetrical one appropriate to a metal such as iron, in the crystals of which the space-lattice is known to be the centred cube. In another model (Fig. 3) the Rutherford-Bohr conception of an atom with large electron orbits is realised. The orbits are represented by elliptically shaped coils with the nucleus of the atom at their

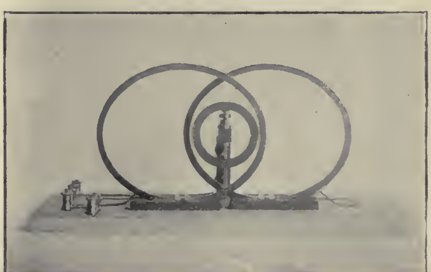

FIG. 3.

common focus: one of them is circular and turns under the control of the others, which are fixed.

Sir Alfred Ewing went on to show that with these models it is possible to imitate known features in the magnetic behaviour of metals, including effects of stress and temperature, and also effects due to the presence of non-magnetic atoms in a ferromagnetic substance, whether these were impurities or were present in combination with the metal. It was pointed out that the new model preserves all the advantages in this respect of his model of 1890 and at the same time escapes the quantitative discrepancy which had made it necessary to amend the former theory.

The Profession of Chemistry.

AT the forty-fourth annual general meeting of the Institute of Chemistry held on March 1 the president, Mr. A. Chaston Chapman, presented the first Meldola medal to Dr. Christopher Kelk Ingold. The medal, which is the gift of the Society of Maccabæans, has been instituted as a memorial to Prof. Raphael Meldola, a past-president of both the Institute and the Society, and is awarded for meritorious original work in chemistry conducted by British subjects under thirty years of age.

In the course of his presidential address Mr. Chaston Chapman said that owing to a variety of causes—foremost among which must be placed the intensive educational effect of the great war—the importance of chemistry to the national well-being was daily becoming more widely and more clearly recognised, and with that recognition had come a great development of the work of the Institute. The roll of members had increased during the past twelve months by 371 to more than 3540, and the students by 84 to 883. The organisation of the profession of chemistry was thus being steadily effected. The older members had the satisfaction of seeing the Institute placed on a sure foundation and its position as the body truly representing professional chemistry in this country, acknowledged alike by chemists, by the general public, and by the Government.

Referring to the scheme recently inaugurated under arrangements made with the Board of Education for the award of National Certificates in chemistry to students in technical schools in England and Wales, the president remarked on the advantage of bringing such students at an early age into touch with the professional qualifying body. Later, when the scheme was in operation, the council of the Institute would consider whether, and to what extent, the certificates should be allowed to rank towards the fulfilment of the conditions required for admission to the examination for the Associateship of the Institute.

In an open and comparatively young profession such as chemistry it was necessary that the public should understand clearly the nature of the work in which the members were engaged. He did not believe that any single cause had contributed so greatly to retarding in the past the progress of the profession of chemistry in this country as the misapplication of the word *chemist*. In no other country was there any confusion between the person who practised chemistry and the person who followed the profession of pharmacy, and continental chemists often expressed their inability to understand what they no doubt regarded as one of our many national peculiarities. For the present the members had to be content to express the hope that their friends the pharmacists, without relinquishing their rights, would, wherever possible, refer to their ancient, important, and very honourable calling by the word which more accurately defined and described it. The power—he might say the tyranny—of a word was often very great, and he appealed to the press, as a very important factor in the enlightenment of the general public, to assist, so far as it could, by employing the terms *chemist* and *pharmacist* respectively in the correct signification. It was to be deplored when such confusion was the unfortunate consequence of the poverty of a language; but, in this instance, the correct and distinctive words were readily available and the confusion was, therefore, easily avoidable. If chemists themselves used the word without qualifying adjectives, it would be an effective step towards establishing the proper meaning of the word.

The war had proved a very powerful factor in informing the public of the activities of the chemical profession, which occupied a position in the public esteem such as he (the president) would not have thought possible in his own lifetime; but every member should help to the best of his ability to consolidate the position they had gained, and to keep alive in the public mind the enormous national importance of the profession. Whether we regarded chemistry as a subject of study, essential to an understanding of the world in which we lived, as an agent which had done so much to transform the life of man, as one of the most powerful factors in the creation of material wealth, or, finally, as that department of natural knowledge on which our national prosperity and our national security so largely depended, its supreme importance was equally manifest.

Commenting on the production of British laboratory glassware, porcelain, and fine chemicals, the president said that the view taken by the council of the Institute and by many others who were desirous of seeing those industries firmly established in this country was that it would be a mistake of the first magnitude to revert to the position of dependence on foreign—and possibly enemy—nations. The whole chemical industry (including those essential to successful conduct of war), the prosecution of scientific research with all that it implies, and the practical teaching of science in schools and universities, all depended upon a supply of laboratory glassware, porcelain, and chemicals, adequate in quantity, suitable in quality, and reasonable in price. On national grounds, it was obviously desirable that the country should be ever directing its activities to production and to the increasing development of its internal resources. There was, moreover, the further consideration, which was much in the minds of the council, that the establishment of these essentially chemical industries demanded the services of properly qualified chemists. British manufacturers had made great progress under difficult circumstances, and there appeared to be no good reason why we should not be self-supporting in all the requirements of the profession.

After complimenting the local sections of the Institute on their activity and acknowledging the help they had given to the council in connection with the work of the Institute, the president commented on the fact that, at a time of almost unparalleled industrial depression, less than two per cent. of the members were without employment. He thought they might draw from this the comforting inference that employers were looking more and more to science to help them in overcoming technical difficulties and in improving their manufacturing operations. He concluded his address, however, with

a note of warning. Many parents still retained the impression that chemistry afforded a rapid road, if not to wealth, at least to a comfortable competence, and that it involved a less expensive course of preparation than for other professions. A keen love of the subject was essential to success; but those who were attracted to chemistry should be prepared to face a great deal of hard and often unattractive work, and to make the very real sacrifice which a professional career inevitably involved. The course of training of the average chemical student was of a university character and made the same demands upon the financial resources of parents as that for medicine and the law.

The present position of the profession should inspire its members with feelings of pride and deep satisfaction, and should stimulate them to increased endeavours to raise it still higher towards that position of pre-eminence which it was surely destined to occupy.

There was scarcely a department of human activity which was not influenced more or less profoundly by the discoveries and developments of chemistry, nor was there a single individual in the community whose comfort had not been increased and whole daily life had not been made happier—or, at least, more tolerable—through the beneficent operations of that science. What discoveries in chemistry the future might hold, and in what way those discoveries might still further modify the material life of man, none could say, but it was not unlikely that if any distinctive term should be applied by the historian of the future to the era on which we were now entering, he would describe it as the "Age of Chemistry."

Biology of Mosquitoes and the Disappearance of Malaria in Denmark.

AN interesting memoir on the biology of Danish Culicidæ has recently been completed by Dr. C. Wesenberg-Lund (Mem. Acad. Roy. Sc. et Lettres de Danemark, Section des Sciences, Series 8, vol. 7, No. 1, 1921). Forty forest-ponds were subjected to regular fortnightly exploration for some years, and from them twenty-five species have been obtained, twenty of which have been reared from larvæ. Among these are four species of Ochlerotatus known from America, but not hitherto found in Europe. Observations on the habits of the larvæ lead the author to support the general conclusion reached by other recent workers that the anal gills are best developed in those larvæ which feed at the bottom of the water. The pupæ are, as every one knows, capable of movement, but they are much more stationary than is usually believed; indeed, the author goes so far as to say that usually there is no locomotion during the whole of the pupal stage. An attempt has been made to work out the life-history of each species of Culicine from the laying of the egg onwards, and the author records many interesting observations. For instance, *Ochlerotatus communis* was found to lay its eggs singly on withered leaves or on the ground underneath these; the eggs are hatched in midwinter or early spring—many of them in April—and the imagines emerge in the first half of May. Mating takes place shortly afterwards, but the craving for blood does not arise until the latter part of June. Eggs are deposited upon dry bottoms from August to December, but do not hatch until they have passed through a period of frost. The biology of *Taeniorhynchus Richardii* also presents features of special interest; the siphon of the larva pierces the submerged roots of aquatic plants and gains access to the air in the intercellular spaces; the siphons of the pupæ are brought into close apposition at their tips and are inserted into submerged roots.

In an important concluding chapter on the three species of Anopheles—*A. plumbeus*, *bifurcatus*, and *maculipennis*, the species found also in this country—the author deals especially with the biology of *A. maculipennis*, well known as the chief carrier of malaria in Europe. He states that in Denmark this species sucks blood from domestic animals—pigs, cattle, horses—that it is seldom seen in the open, but is found, often in incredible numbers, hanging, sluggish and blood-filled, from the ceilings of pigsties, cowsheds, and stables. Only exceptionally does it suck the blood of man, whereas in Mediterranean countries it is an outdoor species feeding largely on human blood. Dr. Wesenberg-Lund considers that in Denmark *A. maculipennis*, which is there living near the northern limit of the range of the species, has ceased to be an outdoor species sucking the blood of man, and has taken to an indoor life and restricted its attacks to farm animals. In his opinion, this change in habits has been the main factor in the disappearance of malaria, the last great epidemic of which took place in Denmark in 1831.

The change in the habits of the mosquito followed an alteration in agricultural methods about a hundred years ago. Whereas previously the swine had been driven to the woods to feed on mast, they and other farm animals were thenceforward housed. The stables, etc., form so many traps which attract mosquitoes by the odour and heat of the animals within, and once within the stable the mosquitoes find all they need until the time arrives for pairing and egg-laying. Thus the connection between man and *A. maculipennis* has been broken in Denmark, and malaria was therefore bound to disappear. The author remarks that if the measurements of the length of this mosquito given by Meigen (1818), when the species presumably fed in the open and largely on man, are correct, there has been an increase in size during the intervening century, though the species is there living near the northern limit of its range.

The Unity of Anthropology.

AT the annual meeting of the Royal Anthropological Institute on January 24 the president, Dr. W. H. R. Rivers, delivered the presidential address, taking as his subject "The Unity of Anthropology."

The aim of the address was to show the unity which underlies the apparently diverse interests of the various branches of anthropology. No student of simple societies can fail to recognise this unity, for the different aspects of culture which are readily distinguished from one another in advanced civilisations are in the simple societies so intertwined and interdependent that it is hopeless to understand any one aspect without studying the whole. It is from the students of more advanced forms of human society that we need a more complete recognition of the unity of anthropology.

The unity of ethnology and archæology was illustrated by means of recent discoveries of the Rev. C. E. Fox in the Solomon Islands, where after the

bodies of the chiefs have been eviscerated they are interred within flat-topped pyramidal mounds, from the surface of which a shaft leads to the recess in which the body is placed. A dolmen is erected on the mound, by the side of which is placed an image in human form designed to receive the soul of the dead chief. These, together with other features, such as the belief in two souls, a cult of the sun with the idea of marriage with the sun, and a tradition of descent from an incestuous union, all connected especially with the chiefly clan, form a body of evidence which shows so many points of resemblance with ancient Egypt in detail that it cannot be neglected by the Egyptologist. It suggests that the rapidly increasing material provided by ethnographical research may help to elucidate some of his most difficult problems.

It was pointed out that it is only in such remote regions as Melanesia, which have not been overrun by later invasions, that we can expect to find survivals of the culture of early voyagers.

The relation between philology and ethnology was illustrated chiefly by reference to phonetics. It was pointed out that in such a region as Melanesia the philologist can now study living examples of transitions and interchanges for the existence of which in Europe his chief evidence is drawn from dead languages, impeded by the limitations which are the necessary result of fixation by means of writing. It was also shown by examples from Melanesia how features of grammar and syntax can be explained as the result of social interactions.

The present barren state of physical anthropology, in so far as it deals with living races, was ascribed to the neglect to utilise the findings of ethnology as working hypotheses and stimuli to new lines of research.

The address concluded with a consideration of the means whereby the Royal Anthropological Institute might promote the recognition of unity. It was pointed out that a scheme, already under consideration, whereby societies dealing with different aspects of human culture should be housed under one roof, with the common use of libraries and lecture-rooms, would contribute to this end; and it was suggested that the Institute itself might give much more attention than it does at present to papers and discussions which would bring out the common purpose of the more specialised studies.

Geology and the History of London.[1]

NUMEROUS small streams now "buried" under London are indicated on the new 6-in. Geological Survey Maps constructed by the author, and the historical research involved in tracing them has led to an appreciation of the connection between the geology and topography on one hand, and the original settlement and gradual growth of London on the other.

The reasons for the first selection of the site have been dealt with by several writers: below London the wide alluvial marshes formed an impassable obstacle; traffic from the Continent came by the ports of Kent, and, if destined for the north or east of Britain, sought the lowest possible crossing of the Thames. This was near old London Bridge, where the low-level gravel on the south and the Middle Terrace deposits on the north approached close to the river-bank. A settlement was obviously required here, and the northern side was chosen as the higher ground. The gravels provided a dry, healthy soil and an easily accessible water-supply; they crowned twin hills separated by the deep valley of the Walbrook, bounded on the east by the low ground near the Tower and the Lea with its marshes, and on the west by the steep descent to the Fleet; the site was, therefore, easily defensible. The river-face of the hills was, naturally, more abrupt than it is now, owing to the reclamation of ground from the river; the most ancient embankment lay 60 ft. north of the northern side of Thames Street.

The first definite evidence of a permanent settlement is the reference in Tacitus. The early Roman encampment lay east of the Walbrook, and the brick-earth on the west around St. Paul's was worked. Later the city expanded until the St. Paul's hill was included, the wall being built in the second half of the fourth century. The great Roman road from Kent (Watling Street) avoided London, and utilised the next ford upstream—at Westminster—on its way to Verulamium and the north-west. The earliest Westminster was a Roman settlement beside the ford, built on a small island of gravel and sand between two mouths of the Tyburn. This settlement could not grow, as did London, since the area of the island, known to the Saxons as Thorney, was small. The road from London to the west joined the St. Albans road at Hyde Park Corner, running along the "Strand," where the gravel came close to the river; a spring thrown out from this gravel by the London Clay was utilised for the Roman Bath in Strand Lane.

Throughout medieval times London was practically confined to the walled city, a defensible position being essential. The forests of the London-Clay belt on the north are indicated in Domesday Book and referred to by several writers, notably Fitzstephen, whose Chronicle also mentions many of the springs and wells and the marsh of Moorfields, produced largely by the damming of the Walbrook by the Wall. The same writer mentions that London and Westminster are "connected by a suburb." This was along the "Strand," and consisted first of great noblemen's houses facing the river and a row of cottages along the north side of the road; this link grew northwards, at first slowly, but in the second half of the seventeenth century with great rapidity. By the end of that period the whole of the area covered by the Middle-Terrace Gravel was built over, but the northern margin of the gravel was also that of the town for one hundred years, the London-Clay belt remaining unoccupied.

The reason for this arrested development was that the gravel provided the water-supply. In early days the City was dependent on many wells sunk through the gravel, some of which were famous, such as Clerkenwell, Holywell, and St. Clement's. In the same way the outlying hamlets (for instance, Putney, Roehampton, Clapham, Brixton, Ealing, Acton, Paddington, Kensington, Islington, etc.) started on the gravel, but later outgrew it. In the City the supply soon became inadequate, or, as Stow says, "decayed," and sundry means were adopted to supplement it. The conduit system, bringing water in pipes from distant springs, began in 1236; London Bridge Waterworks pumped water from the Thames by water-wheels from 1582 to 1817, while the New River was constructed in 1613, and is still in use. It was not until the nineteenth century that steam-pumps and iron pipes made it possible for the clay area to be occupied, thus linking together the various hamlets that now form the metropolitan boroughs of Greater London.

[1] From a lecture delivered before the Geological Society of London on February 1 by C. E. N. Bromehead.

University and Educational Intelligence.

Manchester.—Prof. H. R. Dean, having been appointed to the Chair of Bacteriology in the University of London, has resigned his appointment as Proctor Professor of Pathology.

The University Colston Society has decided to establish, with the aid of industrial firms, a number of Colston Research Fellowships in the faculties of arts, science, medicine and engineering of the University of Bristol. It is proposed to approach firms in the area served by the University with the view of obtaining support for fellowships by the payment of yearly sums of 150*l*., in return for which it would be possible for the donor to earmark the award for a particular branch of study, subject, or person, subject to the approval of the University faculty involved. These fellowships, which will be of the annual value of 150*l*., will be awarded to graduates of the University of Bristol and be tenable for one year. Should no suitable graduate of the University present himself a fellowship may be awarded to a graduate of another university or to any approved person. This scheme comes as an addition to the numerous grants which for many years past have been made by the Colston Society for the encouragement of research in the University of Bristol.

The Association of University Teachers, the president of which is Prof. J. Strong, of the University of Leeds, has issued the first number of a publication, the *University Bulletin* (6*d*.), which it is intended to produce terminally. Its primary object is to serve as the organ of the association, and an editing committee, composed of Prof. J. Strong, Mr. R. D. Laurie, and Mr. F. Smith, is in charge. In an editorial note in the issue before us it is stated that the *Bulletin* will bring to the notice of its readers the doings and policy of the council of the association, and will endeavour to foster the effort to extend the influence of the universities in the life of the nation. Other items which the first issue contains are by Sir Michael Sadler on the threefold allegiance of university teachers to their institution, to the university life of the nation and of the world; an article by Prof. Strong on the aims and activities of the Association of University Teachers; and an historical sketch by Mr. Laurie of the movement which led to the formation of the association. There are also critical notes on the University Grants Committee's Report, Parliamentary representation of teachers, superannuation for university teachers, and similar topics.

Following the lines of previous years, Mr. F. S. Marvin has arranged, in conjunction with Dr. Charles Singer, a course of lectures on "Science and Social Progress," for the Unity History School, to be held at Woodbrooke, Birmingham, from Thursday, July 27, to Friday, August 4. A sketch in broad outline will be given of the history of science, especially in its relation to the contemporary social evolution, and this will be followed, in the latter half, by discourses on the problems that are being raised to-day by the growth of science. First the historical retrospect, then the living problem, and the whole looked at from the completely human point of view. The lecturers will be Prof. J. L. Myres, Dr. J. L. E. Dreyer, Prof. J. A. Platt, Dr. C. Singer, Prof. A. N. Whitehead, Prof. C. H. Desch, Prof. J. A. Thomson, Mr. Julian Huxley, Mr. A. E. Heath, Prof. F. G. Donnan, and Mr. F. S. Marvin. Communications concerning this holiday school should be addressed to Mr. Edwin Gilbert, 78 Mutley Plain, Plymouth. All letters requiring reply should contain stamps covering the necessary postage.

Calendar of Industrial Pioneers.

March 9, 1908. Henry Clifton Sorby died.—Sorby came of an old Sheffield family of cutlers. He was of independent means. Devoting himself to scientific investigations, he became known among geologists as the father of microscopical petrology, while his microscopic study of iron and steel opened out a field of research of immense importance to the metallurgist.

March 10, 1874. Moritz Hermann Jacobi died.—German by birth, Jacobi became a professor at Dorpat and St. Petersburg, where in 1837 he discovered the art of electrotyping. He also improved the voltaic battery, and made a trial on the Neva of a boat driven by an electro motor.

March 10, 1902. Charles Yelverton O'Connor died.—An eminent civil engineer, O'Connor held important positions in New Zealand, and in 1891 became engineer-in-chief to Western Australia. He constructed the harbour at Fremantle, and was responsible for the Coolgardie Water Supply Scheme, in which water is conveyed 328 miles through 30-inch steel pipes, an undertaking costing 2,660,000*l*.

March 11, 1916. Erasmus Darwin Leavitt died.—Trained as a mechanical engineer, Leavitt served in the United States Navy during the Civil War, and afterwards as a consulting engineer was responsible for many of the most important steam-engine installations in America. He was a founder of the American Society of Mechanical Engineers, and in 1883 served as its president.

March 12, 1898. Ferdinand Hurter died.—After serving an apprenticeship to a Swiss dyer, Hurter studied chemistry under Bunsen, and in 1867 settled in England, finally becoming principal chemist to the United Alkali Company. He was a pioneer in the application of mathematics to technological chemistry; and with Driffield carried out a long and fruitful investigation of the chemistry and physics of photography.

March 12, 1914. George Westinghouse died.—A great industrialist, the president of no less than thirty companies, Westinghouse first gained a reputation by his invention of the compressed-air brake for railway trains. Tried in 1868, the brake was made automatic in 1872, and has been universally adopted. Westinghouse was a pioneer in the development of alternating current electric machinery, he assisted Tesla in his work on the induction motor, and made the first ten generators for Niagara.

March 13, 1719. Johann Friedrich Böttger died.—The discoverer of the method of making porcelain from the reddish clays found in the neighbourhood of Meissen, Böttger began life as an apothecary's apprentice in Berlin, but his discovery was largely the outcome of his alchemical experiments. For many years he was maintained as a sort of prisoner by the Elector of Dresden.

March 15, 1898. Sir Henry Bessemer died.—The greatest metallurgist of the nineteenth century, Bessemer, by the invention in 1856 of his direct process of converting pig-iron into malleable iron or mild steel, provided mankind with abundant supplies of a superior structural material at a diminished cost. Several notable metallurgists contributed to the success of the process, which reached its perfection in 1879 by the discoveries of Sidney Gilchrist Thomas.

E. C. S.

Societies and Academies.

LONDON.

Royal Society, March 2.—Sir Charles Sherrington, president, in the chair.—L. N. G. **Filon** and H. T. **Jessop**: On the stress-optical effect in transparent solids strained beyond the elastic limit. The stress-optical effect in glass under simple pressure exhibits no time-effect at ordinary temperatures, but in celluloid under simple tension there is a marked creep in both stress-optical effect and strain even under very moderate loads. The observations can be explained on the assumption that celluloid consists of a mixture of two constituents having different elastic and plastic properties and different stress-optical coefficients, the optical-effect in each being strictly proportional to the stress.—W. E. **Curtis**: The structure of the band spectrum of helium. Measurements of grating photographs of three of the principal helium bands show that the chief features of their structure are accounted for by the quantum theory of band spectra. In each of the three bands a new type of series is found. The spectrum is considered to be due to an unstable helium molecule, having a moment of inertia of about $1 \cdot 8 \times 10^{-40}$ gm.cm.^{2}.—S. **Datta**: The spectrum of beryllium fluoride. The spectrum of beryllium fluoride consists of six groups of bands, all in the ultra-violet between λ 2800 and λ 3400, and all fading off towards the red. The strongest band at λ 3009 includes three series of lines, which depart considerably from the usual type of formula. The groups of bands are similar to one of the groups given by magnesium fluoride.—W. G. **Palmer**: The catalytic activity of copper. Pt. III. The effect upon the catalytic (dehydrogenating) activity of copper of adding to the metal varying proportions of weak dehydrogenating catalysts, ferric, manganous, zinc, and magnesium oxides, is described. Magnesium and manganous oxides enhance the activity of the copper, if present in quantity greater than 1 to 2 per cent., while zinc and ferric oxides reduce the activity. It is considered that small proportions of oxide (less than 1 to 2 per cent.) destroy the activity of the copper, owing to solution in the metal leading to diminished adsorption of the alcohol attacked.—G. B. **Jeffery**: (1) The motion of ellipsoidal particles immersed in a viscous fluid. (2) The rotation of two circular cylinders in a viscous fluid. (1) Einstein has shown that the viscosity of a fluid containing solid spherical particles in suspension is given by $\mu\ (1+2 \cdot 5\ V)$, where μ is the viscosity of the pure fluid and V is the total volume of the particles per unit volume of the suspension. This result is extended to ellipsoidal particles and it is shown that the factor 2·5 is *reduced* but always lies between 2 and 2·5 and depends upon the shape of the particles. (2) The problem of the rotation of a circular cylinder in a fluid contained in a non-concentric cylindrical vessel which may itself rotate about its axis can be solved in finite terms; that of the rotation of two parallel cylinders in an infinite fluid is in general insoluble; *i.e.* there is no steady motion for which the fluid is at rest at infinity.

PARIS.

Academy of Sciences, February 13.—M. Emile Bertin in the chair.—Maurice **Janet**: The characters of the moduli of forms and systems of partial differential equations.—Witold **Wilkosz**: A fundamental point in the theory of potential.—E. **Cartan**: A geometrical definition of the energy tensor of Einstein.—M. **Auric**: The resolution of an indeterminate linear equation.—V. **Dolejsek**: The Kα lines of the lighter elements. The Kα lines have been measured for thirteen elements, ranging between chlorine and zinc.—A. **Dauvillier**: The complexity of the K series of the light elements and its theoretical interpretation. Results and details of measurements in the K series of copper and molybdenum.—C. E. **Guye**: The extension of the law of Paschen to polarised fluids.—M. **Mercier**: Harmonic synchronisation of electrical oscillators.—R. **Bouloch**: Calculation of the elements which determine a centred system formed by any number of surfaces.—A. **Zimmern**: The influence of temperature on the sensibility of emulsions in radiography. Over the range 15° to 80° C. the sensibility of a photographic plate to light varies slightly, if at all. With X-rays, on the other hand, the sensibility increases with rise of temperature, and this effect can in some cases be utilised with advantage. It would appear that the actions of light and X-rays on the silver salt are dissimilar.—C. **Matignon** and M. **Fréjacques**: The transformation of ammonia into urea. Quantitative study of the conversion of ammonium carbamate into urea, alone or in presence of catalysts.—Paul **Pascal**: The magneto-chemical investigation of constitution in mineral chemistry. The phosphoric acids. Measurements of the magnetic susceptibilities are given, and constants deduced for the groups, P, PO_2, PO_3, PO, and PO_4. The results agree with the rational formulæ $PO(OH)_3$ and $RPO(OH)_2$ for the phosphonic and phosphoric acids, and are opposed to $H_2PO(OH)$ for hypophosphorous acid and $HPO(OH)_2$ for phosphorous acid.—E. **Decarrière**: The *rôle* of gaseous impurities in the catalytic oxidation of ammonia. The influence of hydrogen phosphide. Phosphoretted hydrogen poisons the catalyst (platinum) in ammonia oxidation, even in a proportion as low as 0·00002 per cent.—Marcel **Godehot** and Pierre **Bédos**: The oxide of cyclohexene and ortho-methylcyclohexanol. The ether oxide of cyclohexanol is obtained in quantitative yield by the oxidation of cyclohexene with perbenzoic acid. Methylmagnesium iodide reacts with the ether oxide giving *o*-methylcyclohexanol.—V. **Thomas**: A mixed organometallic compound of aluminium. Methylene iodide reacts slowly with aluminium at the ordinary temperature, no gas being evolved.—Alphonse **Mailhe**: A new preparation of amino-naphthenes. Cyclohexanone or its alkyl derivatives are converted into ketazines by reaction with hydrazine hydrate and these reduced to amines by catalytic reduction with nickel. The main product consists of primary amines, with a small proportion of secondary amines as a bye-product.—G. **Meunier**: The action of mineral acids on crude celluloses: the formation and destruction of reducing substances. The utilisation of the bye-products of this destruction. Dilute mineral acids at a high temperature attack the ligno-celluloses as vigorously as strong acids, used cold, with economy of acid. The bye-products include fatty acids, furfurol, acetone, and methyl alcohol, and suggestions are made for their utilisation.—Charles **Jacob**: The structure of southern Tonkin. Except for small differences in detail, the geological structure of southern Tonkin is the same as that of North Annam.—Mlle. Yvonne **Boisse de Black**: Rissian erosion in the high valleys of the Cère and the Goul (Cantal).—P. **Monnet**: The Italian earthquake of September 7, 1920. A slight shock on September 6 was followed on the 7th by a disastrous earthquake by reason of which 250 lives were lost. The seismic zone is a rough oval the major axis of which is S.E.–N.W. and about 50 kilometres long.—C. and M. **Schlumberger**: Electrical phenomena produced by metallic deposits. It has been shown in an earlier communication that deposits of pyrites produce spontaneously differences of potential with the surrounding layers. The

phenomenon appears to be general and the presence of pyrites is not indispensable, similar effects being traced to the presence of galena, mispickel, sulphides of copper, pyrolusite, and other minerals. The effect can be reproduced in the laboratory.—Paul **Guérin**: The mucilage of the Urticaceæ. Mucilage is widely distributed in this order, and its presence in the various organs of these plants constitutes a character of real value, and should be taken into account along with other anatomical peculiarities.—H. **Jumelle**: The Neophloga, Madagascan palm trees.—A. **Guilliermond** and G. **Mangenot**: The signification of Holmgren's canals.—Eugène **Bonnet**: The action of soluble salts of lead on plants. The plants studied included wheat, peas, and beans, and the lead solution surrounding the rootlet between one-thousandth normal and half that amount of lead. Lead arrests the growth of the stem and diminishes the length of the roots.—Gabriel **Bertrand** and Mme. M. **Rosenblatt**: The variations in the proportions of manganese in leaves with age.—Gustave **Rivière** and Georges **Pichard**: The partial sterilisation of the soil. Experiments on the use of sodium arsenate for the partial sterilisation of the soil. Used in the proportion of between 21 and 42 kilograms per hectare the protozoa are destroyed and the useful bacteria multiply. This indirect fertilising action is shown by increased yields, which on the large scale have been shown to be 20 per cent. to 50 per cent.—Auguste **Lumière** and Henri **Couturier**: The resistance of females during pregnancy to anaphylactic and anaphylactoid shock. Female guinea-pigs during pregnancy are immune from shock caused either by the injection of serum or of flocculent inert material. The cause of the immunity has been traced to the increase in the volume of the blood: the immunity could be destroyed in females by bleeding and conferred on males by injecting physiological serum.—M. **Champy**: The conditions of the genesis of the sexual harmozone in Batrachians.—Henri Jean **Frossard**: Respiratory gymnastics and the tests of Valsalva and of Muller.—Foveau de **Courmelles**: Combined radiotherapy of the breast and the ovaries against tumours of the breast.

Diary of Societies.

FRIDAY, March 10.

Royal Astronomical Society, at 5.
Physical Society of London (at Imperial College of Science and Technology), at 5.—R. L. Smith-Rose: The Electromagnetic Screening of a Triode Oscillator.—Dr. H. P. Waran: A New Form of High Vacuum Automatic Mercury Pump.—W. N. Bond: Viscosity Determination by means of Orifices and Short Tubes.
Malacological Society of London (at Linnean Society).
Royal Society of Medicine (Clinical Section), at 5.30.—Prof. H. Maclean and Dr. I. Jones: Some Observations on the Production of Lactic Acid in Stomach Diseases.
Junior Institution of Engineers, at 8.—C. H. Plant: Friction.
Royal Society of Medicine (Ophthalmology Section), at 8.30.—P. G. Doyne: Coloured Vision.—R. A. Greeves: A Series of Sympathising Eyes examined Microscopically.
Royal Institution of Great Britain, at 9.—Prof. T. R. Merton: Problems in the Variability of Spectra.

SATURDAY, March 11.

Royal Institution of Great Britain, at 3.—Sir Ernest Rutherford: Radioactivity (2).

MONDAY, March 13.

Royal Geographical Society (at Lowther Lodge, Kensington Gore, S.W.7), at 5.—C. C. Fagg: A Description of the Regional Survey of the Croydon Natural History and Scientific Society.
Royal Society of Medicine (War Section), at 5.30.—Squadron Leader H. E. Whittingham: Observations on Sandfly Fever in Malta.
Institute of Transport (at Institution of Civil Engineers), at 5.30.—T. R. Johnson: Railway Problems in China and Australia.
Medical Society of London (at 11 Chandos Street, W.1), at 8.—Dr. E. W. Goodall: The Differential Diagnosis of the Common Exanthemata.

TUESDAY, March 14.

Royal Institution of Great Britain, at 3.—Sir Arthur Keith: Anthropological Problems of the British Empire. Series I. Racial Problems in Asia and Australasia (4).
Royal Society of Medicine (Therapeutics and Pharmacology Section) (at University College), at 4.30.
Eugenics Education Society (at Royal Society), at 5.—H. Cox: The Reduction of the Birth Rate as a Necessary Instrument for the Improvement of the Race.
Royal College of Physicians of London, at 5.—Dr. M. Greenwood: The Influence of Industrial Employment on General Health (Milroy Lectures) (2).
Royal Sanitary Institute (90 Buckingham Palace Road, S.W.1), at 5.30.—A. H. Barker, and others: Central Heating in Relation to Domestic and other Buildings.
Women's Engineering Society (at 26 George Street, W.1), at 6.15.—F. S. Button: Women's Place in Industry.
Institution of Petroleum Technologists (at Royal Society of Arts), at 6.30.—Prof. J. S. S. Brame: Presidential Address.
Royal Photographic Society of Great Britain, at 7.—Annual General Meeting.
Quekett Microscopical Club, at 7.30.—B. S. Curwen: Mounting in Glycerine with Wax Seals, with Special Reference to Entomostraca.
Royal Anthropological Institute, at 8.15.—J. P. Mills: The Lhota Nagas.
Royal Society of Medicine (Psychiatry Section), at 8.30.—Adjourned Discussion on the Ideal Clinic for Nervous and Borderland Cases.

WEDNESDAY, March 15.

Royal Society of Medicine (History of Medicine Section), at 5.—F. Romer: A Short History of Bonesetting.
Institution of Civil Engineers (Students' Meeting), at 6.—G. FitzGibbon: The Great Ship-Canals of the World (Vernon Harcourt Lectures) (1).
Royal Meteorological Society, at 7.30.—Dr. E. M. Wedderburn: Seiches; and the effect of Wind and Atmospheric Pressure on Inland Lakes.

ROYAL SOCIETY OF ARTS, at 8.—O. T. Falk: Certain Aspects of the Problem of Exchange Stabilisation.
ENTOMOLOGICAL SOCIETY OF LONDON, at 8.
ROYAL MICROSCOPICAL SOCIETY, at 8.—J. E. Barnard: The Future of the Microscope in Medical Research.—Dr. H. Hartridge: Monochromatic Illumination. A Low-Power Eyepiece with Large Field.

THURSDAY, MARCH 16.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. P. C. Mitchell: The Cinema as a Zoological Method (1).
ROYAL SOCIETY, at 4.30.—*Probable Papers.*—Dr. H. H. Dale and C. H. Kellaway: Anaphylaxis and Anaphylatoxins.—J. C. Bramwell and Prof. A. V. Hill: The Velocity of the Pulse Wave in Man.—A. Fleming: A New Bacteriolytic Element found in Tissues and Secretions.—Dr. J. W. Pickering and Dr. J. A. Hewitt: The Action of "Peptone" on Blood and Immunity thereto.
LINNEAN SOCIETY OF LONDON, at 5.—B. M. Griffiths: The Heleoplankton of Three Berkshire Pools.—C. E. Salmon: Three British Plants.—Rev. F. C. R. Jourdain: Bear Island and Spitzbergen, with especial regard to their Bird-life.
ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. M. Greenwood: The Influence of Industrial Employment on General Health (3).
ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.30.—Dr. V. E. Pullin: Radiological Examination of Materials.
INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.—L. C. Stuckey: Notes on the Valuation of Ores, Concentrates and Smelter Products.—L. H. Cooke: Methods of Measuring Horizontal Angles involving Steep or Precipitous Sights.
INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—J. G. Hill: Phantom Telephone Circuits and Combined Telegraph and Telephone Circuits worked at Audio Frequencies.
CHEMICAL SOCIETY, at 8.—H. B. Baker: Change of Properties of Substances on Drying.—H. Burton and J. Kenner: The Influence of Nitro-Groups on the Reactivity of Substituents in the Benzene Nucleus. Part VI. The Elimination of Halogen during the Reduction of Halogenated Nitro-Compounds.
SOCIETY FOR CONSTRUCTIVE BIRTH CONTROL AND RACIAL PROGRESS (at Essex Hall, Essex Street, W.C.2), at 8.—Open Meeting.
ROYAL SOCIETY OF MEDICINE (Dermatology Section), at 8.30.—Dr. J. Darier: Des cancers épithéliaux de la peau.

FRIDAY, MARCH 17.

ROYAL SOCIETY OF MEDICINE (Otology Section), at 5.
INSTITUTE OF TRANSPORT (at Royal Society of Arts), at 5.—F. Pick: The Operation of an Omnibus Company, with reference to Capacity and Cost under Given Conditions.
INSTITUTION OF MECHANICAL ENGINEERS, at 6.—P. C. Dewhurst: British and American Locomotive Design and Practice.
INSTITUTION OF ELECTRICAL ENGINEERS (London Students' Section), at 7.—C. C. H. Wade: The Electron Theory.
JUNIOR INSTITUTION OF ENGINEERS, at 8.—G. H. Ayres: Power Factor Improvement.
ROYAL SOCIETY OF MEDICINE (Electro-therapeutics Section), at 8.30.—Dr. M. Legge and others: Discussion on the Pathological Changes produced in Subjects rendered Unconscious by Electric Shock, and the Treatment.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Principal A. P. Laurie: The Pigments and Mediums of the Old Masters.

SATURDAY, MARCH 18.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: Radioactivity (3).
PHYSIOLOGICAL SOCIETY (at University College).

PUBLIC LECTURES.

(*A number in brackets indicates the number of a lecture in a series.*)

FRIDAY, MARCH 10.

METEOROLOGICAL OFFICE (South Kensington, S.W.7), at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (8).
TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES (at Mary Ward Settlement, Tavistock Place, W.C.1), at 5.30.—Dr. H. C. Miller: The New Psychology and its Bearing on Education (7).

SATURDAY, MARCH 11.

LONDON DAY TRAINING COLLEGE, at 11.—Prof. J. Adams: The School Class (8).
HORNIMAN MUSEUM (Forest Hill), at 3.30.—Miss M. A. Murray: Cleopatra's Needle and Sun-worship.

TUESDAY, MARCH 14.

IMPERIAL COLLEGE (Royal School of Mines), at 5.30.—Col. N. T. Belalew: The Crystallisation of Metals (4).

WEDNESDAY, MARCH 15.

EAST LONDON COLLEGE, at 4.—Prof. F. E. Fritch: Certain Aspects of Freshwater Algal Biology (5).
LONDON (R.F.H.) SCHOOL OF MEDICINE FOR WOMEN (Hunter Street, W.C.1), at 5.—Dr. H. H. Dale: Some Recent Developments in Pharmacology (4).
KING'S COLLEGE, at 5.15.—Prof. N. Bohr: The Quantum Theory of Radiation and the Constitution of the Atom (2).
HORNIMAN MUSEUM (Forest Hill), at 6.—W. W. Skeat: The Living Past in Britain (8).
UNIVERSITY COLLEGE, at 8.—The Current Work of the Biometric and Eugenics Laboratories (5). Julia Bell: The Inheritance of certain Types of Blindness.

THURSDAY, MARCH 16.

SCHOOL OF ORIENTAL STUDIES, at 5.—Dr. L. D. Barnett: The Hindu Culture of India (3).
UNIVERSITY COLLEGE, at 5.15.—Prof. J. E. G. de Montmorency: Welsh and Irish Tribal Customs (6).
KING'S COLLEGE, at 5.30.—Dr. O. Faber: Reinforced Concrete (9).
LONDON DAY TRAINING COLLEGE, at 6.—Dr. W. Rosenhain: Aluminium and its Alloys.

FRIDAY, MARCH 17.

METEOROLOGICAL OFFICE (South Kensington), at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (9).
KING'S COLLEGE, at 5.—Prof. R. Robinson: Orientation and Conjugation in Organic Chemistry from the Standpoint of the Theories of Partial Valency and of Latent Polarity of Atoms (3).
TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES (at Mary Ward Settlement, Tavistock Place, W.C.1), at 5.30.—Dr. H. C. Miller: The New Psychology and its Bearing on Education (8).

SATURDAY, MARCH 18.

THE POLYTECHNIC (Regent Street, W.1), at 10.30 A.M.—P. A. Best: The Romance of Commerce.
HORNIMAN MUSEUM (Forest Hill), at 3.30.—H. N. Milligan: The Natural History of Elephants.

CONTENTS.

THURSDAY, MARCH 16, 1922.

Editorial and Publishing Offices:
MACMILLAN & CO., LTD.,
ST. MARTIN'S STREET, LONDON, W.C.2.

Advertisements and business letters should be addressed to the Publishers.
Editorial communications to the Editor.

Telegraphic Address: PHUSIS, LONDON.
Telephone Number: GERRARD 8830.

The Melbourne University Bill.

MELBOURNE University early took high rank among the universities of the British Dominions by the special distinction of many of its staff, the high standard of its degrees, and the harmonious co-operation between it and its affiliated colleges. There has, however, been a feeling in recent years among educationists in Victoria that the university is not still of the same standing, as it had not kept pace with progress elsewhere. To remove the causes of any such decline the Government of Victoria has introduced a Bill raising the statutory grant to the university from 21,000*l.* per annum to 30,000*l.*, the amount stated as necessary by the university council. This Bill also proposes reforms in the constitution of the university.

The ultimate authority at present is the senate, which consists of all the graduates of the university holding the degree of doctor or master. This body has some legislative powers and elects practically the whole of the university council, which is the executive and administrative organ of the university. To give such authority to the senate was probably the soundest policy available at the foundation of the university, but it is no longer necessary. The new Bill therefore proposes to replace the senate by a convocation which would consist of all the graduates, would act through a committee, and would elect twelve out of the thirty members of the council. The Bill reconstitutes the council to make it more widely representative. The new council would consist of thirty members, seven appointed by the Government, two by the university staff, and one by the students, and would include the director of education and the president of the Professorial Board *ex officio*. These members and the twelve elected by convocation would co-opt the six remaining members.

The new Bill assigns to the university three additional branches of work, a school of commerce, research at the university in applied science, and a university extension department; and it allots for these purposes an extra grant of 7000*l.* per annum. The allocation to the university of the proposed educational extension work would seem to be to its advantage as well as to that of the State. There is a widespread reaction towards various forms of affiliation as a means of widening the influence of universities on national education; but this system often imposes a severe burden on a university, and is better not employed if some other way of organising higher provincial education be available. In the case of Victoria, failing the scheme proposed in the Bill, the alternatives are the organisation of super-secondary classes by the Education Department, or the award of university degrees to external students by examination, the course recently adopted in Western Australia and Queensland. The proposal in the Bill for the admission of fifty free students a year to the university would therefore seem to be to its ultimate benefit, by lessening any claim for affiliation that might be put forward in future by provincial institutions.

The lines of the new Bill follow the present general trend of university reform. The University Association of Teachers, of which Prof. W. A. Osborne, the president of the Professorial Board, is chairman, has, however, issued a statement expressing great anxiety and disappointment at some of its features. The criticisms complain especially of the inadequate representation of the university staff on the new council, and of the disregard of the principle that a university should not be called upon to undertake new duties until the old duties are properly provided for. The statement points out that the 9000*l.* added to the annual grant for general university purposes would be so reduced by new expenses and loss of revenue from fees and public examinations that the university would gain at the utmost only an extra 1200*l.* If these estimates be correct, this additional income is obviously quite insufficient to enable the university to cope with the inrush of new students, who increased in numbers from 1296 in 1914 to 2607 in 1921.

This criticism is less against the Government than against the university council, which, according to the Association of University Teachers, has failed to protect the interests of the university by not raising fees and by asking for an inadequate increase of the State grant. The Government has given the amount

said to be necessary, and has probably under-estimated the effects on the university income of some of the proposed changes. If these effects be demonstrated, the raising of the general university grant may be expected.

The discussion of the new Bill shows that university teachers in Australia are profoundly anxious as to the present conditions, are doubtful of the possibility of maintaining the university work at an appropriate level, and are alarmed at the discontent rife among all grades of the staff. It is impossible for any one not intimately acquainted with existing conditions in Australia to judge the financial estimates, but it is obvious that if a university staff is thoroughly discontented its efficiency is bound to suffer. Teachers who are not paid a living wage must supplement their income by outside work which, except perhaps in departments of applied science, inevitably detracts from their usefulness to the university.

Those interested in the progress of the universities of the British Empire will hope that the Victorian Government, before the new Bill is passed, will allay the distracting anxieties of the university staff by making sure that the nominal increase of 30 per cent. in the general purposes grant is an actual increase of this amount, and by amending the regulations relating to the council so as to guarantee a larger representation of university teachers. The provision that one of the six members to be co-opted by the council and two of the twelve to be elected by convocation must be university teachers would give a staff representation of one in five, which is the average in the younger British universities. If by such changes the new scheme gained the confidence of the staff the reforms would restrengthen the university, which has hitherto been a glory to the State of Victoria and an important asset in the development of Australia.

Greek Mathematics.

A History of Greek Mathematics. By Sir Thomas Heath. Vol. 1, *From Thales to Euclid*. Pp. xv +446. Vol. 2, *From Aristarchus to Diophantus*. Pp. xi+586. (Oxford: Clarendon Press, 1921.) 2 vols., 50*s*. net.

WERE this book only for the mathematician it would be no book for me; but it is a great deal more. It is for all who care for the historical aspect of science; it is for all lovers of Greek, for mathematics is a true "Legacy of Greece," and is interwoven through and through with Greek thought and philosophy.

A couple of accidents in boyhood (if I may be allowed the reminiscence) made this subject curiously attractive to me. George Johnston Allman, pioneer in this country of the renewed study of Greek geometry, belonged to the little band of scholarly professors who taught in those days in Galway College; he had more of mathematics and more of fine historic sense than of Greek letters, and here his colleagues—"Tom" Maguire the Platonist, Davies the editor of the *Eumenides*, and my father, who was his kinsman—combined to help him. In our quiet Galway life we heard for months together little else than of Allman's book and the long discussions which went to the making of it.
